ABSTRACT:

We investigated the quantitative prediction of human hepatic metabolic clearance from in vitro experiments focusing on cytochrome P450 metabolism with eight model compounds, FK1052, FK480, zolpidem, omeprazole, nicardipine, nilvadipine, diazepam, and diliazem. For the compounds, in vivo human hepatic extraction ratios ranged widely from 0.03 to 0.87. In vitro and in vivo hepatic intrinsic clearance (CLint) values for each compound were measured and calculated in rats and/or dogs and humans. CLint,in vitro was determined from a substrate disappearance rate at 1 μM in hepatic microsomes, which was a useful method. CLint,in vivo was calculated from in vivo pharmacokinetic data using three frequent mathematical models (the well stirred, parallel-tube, and dispersion models). The human scaling factor values (CLint,vivo/CLint,in vitro) showed marked difference among the model compounds (0.3–26.6-fold). On the other hand, most of the animal scaling factors were within 2-fold of the values in humans, suggesting that scaling factor values were similar in the different animal species. When human CLint,in vitro values were compared with the actual CLint,vivo correlation was not necessarily good. By contrast, using human CLint,in vitro corrected with the rat and/or dog scaling factors yielded better predictions of CLint,vivo that were mostly within 2-fold of the actual values. Furthermore, successful predictions of human CLoral and hepatic extraction ratio (Eh) were obtained by the use of human CLint,in vitro corrected with animal scaling factors. The new variant method is a simple one, incorporating additional information from animal studies and providing a more reliable prediction of human hepatic clearance.

In recent years, the process of drug discovery and development has become an increasingly time-consuming and costly endeavor. Much of the time and cost are expended on generating data that support the efficacy and safety profiles of the drug. Safe and efficient drug candidates must therefore be selected before clinical trials.

On the other hand, there is growing awareness of the key roles that pharmacokinetics and drug metabolism play as determinants of in vivo action. In these situations, early pharmacokinetic investigation plays an increasingly important role in the optimization and selection of drug candidates. In particular, it is important to predict human hepatic metabolic clearance because many drugs are eliminated from the body by hepatic metabolism. For predicting hepatic clearance, theoretical aspects of in vitro/in vivo scaling, based on a physiological model and clearance concepts, have been developed (Rane et al., 1977; Lin et al., 1982; Roberts and Rowland, 1986; Wilkinson, 1987).

Application of this method has been successful in predicting in vivo hepatic clearance in rats for many drugs metabolized by P4501 from in vitro metabolism data using rat liver microsomes and isolated hepatocytes (Sugiyama et al., 1988; Houston, 1994). Since human liver samples have become more readily available, it would also be very useful to predict in vivo from in vitro data in humans. However, there has been relatively limited application of this approach (Hoener, 1994; Iwatsubo et al., 1997b), and there have been many failed attempts at predicting human hepatic clearance. For example, Iwatsubo et al. (1997a) reported a comparison of CLoral and CLint,vivo for 25 metabolic reactions in humans from literature data. According to the report, although CLoral and CLint,vivo generally exhibited a positive correlation with CLoral more than a 3-fold difference was observed in CLoral for about 50% of the 25 metabolic reactions. Houston and Carlile (1997) also compared CLoral and CLint,vivo obtained from in vitro experiments using rat liver microsomes with CLoral for 28 drugs metabolized by P450. Although the predictability of CLoral from in vitro data was good overall, the results of some of the drugs tended to be low estimates. To improve the predictions of human hepatic clearance, a few investigators have described new methods and approaches. For example, Lave et al. (1997) have proposed the allometric scaling techniques combined with in vitro data.
reported that inclusion of microsome binding values in the prediction of clearance from in vitro data appears to be a more broadly applicable approach.

In the present study, we have examined in vitro and in vivo metabolic clearance of eight model compounds, FK1052, FK480, zolpidem, omeprazole, nicardipine, nilvadipine, diazepam, and diltiazem, and calculated the CL_{int,in vivo} and CL_{int,in vitro}, using in vitro and in vivo metabolism data in rats, dogs, and humans. At the same time, the measurement method of CL_{int,in vivo} which is determined from a substrate disappearance rate at 1 μM in hepatic microsomes, was used as a simple and useful method. We have also compared the parameters and evaluated a quantitative prediction method of human hepatic clearance focusing on P450 in drug discovery.

**Materials and Methods**

**Chemicals.** FK1052, FK480, and nilvadipine were synthesized by Fujisawa Pharmaceutical Co., Ltd. (Osaka, Japan). Zolpidem hemitartrate and omeprazole sodium were kindly provided by Fujisawa-Synthelabo Pharmaceuticals (Tokyo, Japan) and Astra Japan Ltd. (Osaka, Japan), respectively. Diltiazem hydrochloride and nicardipine hydrochloride were purchased from Sigma Chemical Co. (St. Louis, MO). Diazepam was purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). NADP⁺, 10 mM glucose-6-phosphate, 0.4 U/ml glucose-6-phosphate dehydrogenase, and 5 mM MgCl₂ in the presence of 100 mM potassium phosphate buffer (pH 7.4). After preincubation at 37°C for 5 min, enzyme reactions were initiated by adding 5 μl of model compound solution in methanol. The final concentration of each model compound used was 1 μM. The microsomal concentrations used were 0.2 mg/ml (nicardipine, nilvadipine, and diltiazem), 0.5 mg/ml (FK1052, zolpidem, omeprazole, and diazepam), and 1.0 mg/ml (FK480). After incubation at 37°C for various time periods, the reactions of FK1052, FK480, omeprazole, zolpidem, and diltiazem were terminated by the addition of 500 μl of acetonitrile. The reactions of nicardipine and nilvadipine were terminated by adding 500 μl of methanol and 3 ml of ethyl acetate, respectively. After stopping the metabolic reactions, the reaction mixtures of FK1052, FK480, omeprazole, zolpidem, nicardipine, diltiazem, and diazepam were centrifuged at 10,000 g for 5 min, and an aliquot of the supernatant was injected on an HPLC for measuring the unchanged compound concentration. The reactions of nilvadipine were processed by extraction. The organic fraction was evaporated under N₂, and the residue was reconstituted in the mobile phase (see below) for HPLC analysis.

**Determination of unchanged model compound concentrations.** An LC module I plus (Millipore Co., Milford, MA) was used. The column for the analysis was an Inertsil ODS-3 (5 μm, 150 × 4.6 mm) (GL Science, Inc., Tokyo, Japan). The flow rate was 1.0 ml/min. The mobile phase and detection wavelength for the analysis of each model compound was as follows: FK1052, FK480, mobile phase: buffer A/CH₃ CN (40:60), detection: UV 242 nm; Nilvadipine, mobile phase: buffer A/CH₃ CN (33:67), detection: UV 240 nm; Diazepam, mobile phase: buffer A/CH₃ CN (40:60), detection: UV 245 nm; Diltiazem, mobile phase: buffer A/CH₃ OH (35:65), detection: UV 254 nm; Omeprazole, mobile phase: buffer A/CH₃ CN (50:50), detection: UV 254 nm; Zolpidem, mobile phase: buffer A/CH₃ CN (50:50), detection: UV 254 nm; Nilvadipine, mobile phase: buffer A/CH₃ CN (33:67), detection: UV 254 nm; Diazepam, mobile phase: buffer A/CH₃ CN (50:50), detection: UV 210 nm.

All assay methods showed the concentration range of 0.1 to 2 μM. Reproducibility was evaluated by performing five replicate analyses of microsomal samples containing 0.1, 0.5, and 1 μM compound, respectively. The coefficient of variation was less than 10%, and the actual concentration of the compounds ranged from 88 to 112.1%. All assay methods thus provide good accuracy and precision.

**Calculation of CL_{int,in vivo}.** CL_{int,in vivo} values were calculated from the substrate disappearance rate in hepatic microsomes as follows. If substrate disappearance can be assumed to follow a first-order reaction, the unchanged drug profile as a function of time [C(t)] is described as follows:

\[ C(t) = C_0 \cdot \exp(-k \cdot t) \]  

(1)

Although it has been reported that diltiazem is metabolized in part by liver microsomal esterase in rats (LeBoeuf and Grech-Belanger, 1987), the compound was examined for reference.

**Hepatic Microsomes.** Liver specimens from adult male Sprague-Dawley rats (250–270 g, n = 3; Charles River Japan Inc., Yokohama, Japan) and adult male dogs (9.5–10 kg, n = 3; Japan Laboratory Animals, Inc., Tokyo, Japan) were rinsed and homogenized with ice-cold 1.15% KCl. These pooled microsomes were prepared by differential centrifugation, and the 105,000 g pellet was rinsed and resuspended in 1.15% KCl. Pooled human microsomes were obtained from Human Biologics International (Scottsdale, AZ). The pooled human microsomes were prepared from 15 individual liver donors that were selected on the basis of having average activities for the major P450 isozymes (1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, 3A4, and 4A11). Each suspension was divided into aliquots, frozen, and stored at −80°C until used.

**In Vitro Metabolism in Microsomes.** In vitro experiments. The time courses of the unchanged model compounds in microsomes were obtained. Each compound was incubated with a reaction mixture (500 μl) consisting of animal or human liver microsomal protein and NADPH-generating system (2 mM NADP⁺, 10 mM glucose-6-phosphate, 0.4 U/ml glucose-6-phosphate dehydrogenase, and 5 mM MgCl₂) in the presence of 100 mM potassium phosphate buffer (pH 7.4). After preincubation at 37°C for 5 min, enzyme reactions were initiated by adding 5 μl of model compound solution in methanol. The final concentration of each model compound used was 1 μM. The microsomal concentrations used were 0.2 mg/ml (nicardipine, nilvadipine, and diltiazem), 0.5 mg/ml (FK1052, zolpidem, omeprazole, and diazepam), and 1.0 mg/ml (FK480). After incubation at 37°C for various time periods, the reactions of FK1052, FK480, omeprazole, zolpidem, nicardipine, and diltiazem were terminated by the addition of 500 μl of acetonitrile. The reactions of diazepam and nilvadipine were terminated by adding 500 μl of methanol and 3 ml of ethyl acetate, respectively. After stopping the metabolic reactions, the reaction mixtures of FK1052, FK480, omeprazole, zolpidem, nicardipine, diltiazem, and diazepam were centrifuged at 10,000g for 5 min, and an aliquot of the supernatant was injected on an HPLC for measuring the unchanged compound concentration. The reactions of nilvadipine were processed by extraction. The organic fraction was evaporated under N₂, and the residue was reconstituted in the mobile phase (see below) for HPLC analysis.

**Calculation of CL_{int,in vitro}.** CL_{int,in vitro} values were calculated from the substrate disappearance rate in hepatic microsomes as follows. If substrate disappearance can be assumed to follow a first-order reaction, the unchanged drug profile as a function of time [C(t)] is described as follows:

\[ C(t) = C_0 \cdot \exp(-k \cdot t) \]  

(1)
where $C_0$ is initial concentration of the compound, and $k_e$ is the disappearance rate constant of unchanged drug (per minute).

Furthermore, initial metabolic rate ($V_0$) per unit milligram of microsomal protein (μmol/min/mg microsomal protein) is described by eq. 2.

$$V_0 = k_e \cdot C_0 / P_{MS}$$

where $P_{MS}$ is the microsomal protein concentration (mg/ml).

On the other hand, from the Michaelis-Menten equation, $V_0$ is described by eq. 3.

$$V_0 = V_{max} \cdot C_0 / (K_m + C_0)$$

If the substrate concentration used in the experiments (1 μM) is below the $K_m$ for the P450-mediated reactions, the drug concentration may be assumed to be much smaller than $K_m$ ($K_m \gg C_0$). Thus, $V_0$ can be expressed by eq. 4.

$$V_0 = V_{max} / K_m \cdot C_0$$

Consequently,

$$CL_{int,in vitro} = V_{max} / K_m = V_0 / C_0$$

$CL_{int,in vitro}$ was thus calculated by eq. 5 based on the time course of unchanged drug concentrations by least square linear regression. The $CL_{int,in vitro}$ values expressed per milligram of microsomal protein calculated from the in vitro metabolism experiments were expressed per kilogram of body weight by taking the microsomal protein content per gram liver and the liver weight per kilogram of body weight shown in Table 1 into consideration.

In Vivo Data. Sources of pharmacokinetic data. In vivo clearance under linear conditions, $f_a$ and $R_B$ data, were obtained from in house and literature. The in vivo pharmacokinetic data were considered to be reliable since the in vivo human $CL_{int,in vivo}$ predictions, success was assessed by the geometric mean of the ratio of predicted and actual values (Obach, 1999). Thus:

$$
\text{Average fold error} = 10\log [\text{mean of predicted}] / [\text{true}]
$$

Prediction of in vivo human $CL_{oral}$ and $E_H$. In vivo human $CL_{oral}$ and $E_H$ were predicted using eqs. 6 to 14, based on the human $CL_{int,in vitro}$ corrected with animal scaling factor. $CL_{oral}$ of FK1052, FK480, and zolpidem were absorbed at 37°C for 4 h. After an incubation period, the microsome and buffer samples were removed and analyzed by HPLC.

Calculation of $CL_{int,in vitro}$. $CL_{int}$ values were determined from eq. 6 by use of the $CL_{oral}$ values, except the $CL_{int}$ for omeprazole in dogs, where only $CL_{oral}$ data was available. $CL_{int}$ was considered to be negligible for the model compounds.

$$CL_{int} = CL_{oral} / R_B \cdot (1 - F_{B})$$

$CL_{int,in vitro}$ was calculated from the following equations using the well stirred, parallel-tube (Pang and Rowland, 1977), and dispersion models (Roberts and Rowland, 1986).

$$CL_{int} = Q_H \cdot (1 - F_{B})$$

Well stirred model:

$$F_H = Q_H / (Q_H + (f_a / R_B) \cdot CL_{int})$$

Parallel-tube model:

$$F_H = \exp[-(f_a / R_B) \cdot CL_{int}]$$

Dispersion model:

$$F_H = \frac{4a}{(1 + a)^2 \exp[(a - 1)/2D_H] - (1 - a) \exp[-(a + 1)/2D_H]}$$

$$a = (1 + 4R_B / D_H)^{1/2}$$

$$R_B = (f_a / R_B) \cdot CL_{oral} / Q_H$$

$$D_H = 0.17$$

$CL_{oral}$ for omeprazole in dogs was calculated from eqs. 7 to 13 by use of the $CL_{oral}$ value, where $CL_{int}$ is equal to $CL_{oral} / R_B$.

$E_H$ were calculated from eq. 14.

$$E_H = 1 - F_{B} = CL_{oral} / Q_H$$

Prediction of Human $CL_{int,in vivo}$. $CL_{oral}$ and $E_H$. Estimation of scaling factor. Values of scaling factor were estimated from the following equation:

$$\text{Scaling factor} = CL_{oral} / CL_{int,in vitro}$$

Prediction of human $CL_{int,in vivo}$. Human $CL_{int,in vivo}$ were predicted based on human $CL_{int,in vitro}$ using the following two methods: 1) disregarding animal scaling factor:

$$\text{Predicted human } CL_{int,in vivo} = CL_{int,in vitro}$$

2) including animal scaling factor:

$$\text{Predicted human } CL_{int,in vivo} = \text{human } CL_{int,in vitro} \cdot \text{animal scaling factor}$$

For these $CL_{int,in vivo}$ predictions, success was assessed by the geometric mean of the ratio of predicted and actual values (Obach, 1999). Thus:

$$\text{Average fold error} = 10\log [\text{mean of predicted}] / [\text{true}]$$

Prediction of in vivo human $CL_{oral}$ and $E_H$. In vivo human $CL_{oral}$ and $E_H$ were predicted using eqs. 6 to 14, based on the human $CL_{int,in vitro}$ corrected with animal scaling factor.

Binding of Model Compounds to Microsomes. Determination of $f_{a, microsome}$. Model compounds (final concentration, 1 μM) were mixed with liver microsomes (at protein concentrations used for the respective metabolic incubations) in 100 mM phosphate buffer (pH 7.4) containing 10 mM glucose-6-phosphate, 0.4 U/ml glucose-6-phosphate dehydrogenase, and 5 mM MgCl₂. The mixtures (1.2 ml) were delivered to one side of a dialysis cell containing a preconditioned dialysis membrane (molecular weight cut off, 10 kDa) (Dainippon Pharmaceutical Co., Ltd., Osaka, Japan). To the other side of the membrane was delivered 1.2 ml of the phosphate buffer containing glucose-6-phosphate and MgCl₂. The cells were sealed, and the apparatus was incubated at 37°C for 4 h. After an incubation period, the microsome and buffer samples were removed and analyzed by HPLC. The HPLC conditions were the same as described above. The unbound fraction was calculated from the following:

$$f_{a, microsome} = \frac{\text{unchanged compound concentration in buffer side}}{\text{unchanged compound concentration in microsome side}}$$

Calculation of $CL_{int,in vitro}$ and the scaling factor. By incorporating the correction with the unbound fraction in the microsomal incubation mixture, $CL_{int,in vivo}$ is defined as (Iwatsubo et al., 1997a):

$$CL_{int,in vivo} = CL_{int,in vitro} / f_{a, microsome}$$

The value of scaling factor, which is $CL_{int,in vivo}$ to $CL_{int,in vitro}$, was calculated from eq. 15.
In Vivo Pharmacokinetic Data of Model Compounds. In vivo pharmacokinetic data for the model compounds are summarized in Table 2. For values were high, in the range of 0.7 to 1.0. The values of unbound fraction in plasma (or serum) (f_p) were relatively low for all compounds ranging from the highest value for diltiazem (f_p: rat, 0.184; dog, 0.298; human, 0.22) to the lowest value for FK480 (f_p: rat, 0.01; dog, 0.006; human, 0.005). In vivo clearance, CL_{int,in vivo}, values calculated using the mathematical models in Fig. 4. Without animal scaling factor consideration, only two (the well stirred model) or three (the parallel-tube and the dispersion models) of eight prediction values were within 2-fold of the actual CL_{int,in vivo}, resulting in a large underestimation for most of the compounds. By contrast, using human CL_{int,in vitro} corrected with rat and/or dog scaling factor, 9 (the parallel-tube model) or 10 (the well stirred and the dispersion models) of 13 prediction values were within 2-fold of the actual CL_{int,in vivo}, significantly improving the predictability of CL_{int,in vivo}.

The geometric mean accuracy values as indices of human CL_{int,in vivo} predictability are listed in Table 4. The value of one means perfect predictability, and the poorer becomes predictability with the larger values. The geometric mean accuracy values without animal scaling factor consideration were 3 to 4. By contrast, the predictability was substantially improved with the geometric mean accuracy value of less than 2.

Furthermore, human in vivo CL_{oral} and E_H values were predicted from human CL_{int,in vitro} corrected with animal scaling factor. Figure 5 presents comparisons of the predicted CL_{oral} values with the observed CL_{oral}. The CL_{oral} values predicted using the well stirred model were in good agreement with the observed values. When CL_{oral} was predicted using the parallel-tube and the dispersion models, good correlations were observed, with the exception of the overestimation for nilvadipine.

Figure 6 shows the relation between CL_{int,in vitro} and in vivo E_H. The predicted E_H based on f_p \cdot CL_{int,in vitro} corrected with animal scaling factor was close to the observed E_H for all mathematical models. This result suggests that the human CL_{int,in vitro} with animal
Scaling factor consideration could give a good prediction of E_H and hepatic clearance in humans.

**Binding of Model Compounds to Microsomes.** Binding experiments were conducted in similar conditions used in in vitro microsomal metabolism studies but were conducted in the absence of NADP⁺ so that metabolism of the compounds would not occur. Recovery of the compounds was more than 90%, except nicardipine where the recovery was about 50%. Table 5 summarizes the unbound fraction in liver microsomes, human CL_{int,in vitro} corrected with f_u,microsome, and the scaling factor values. f_u,microsome of diltiazem in rats could not be estimated because this compound was metabolized by microsomal esterase (see Materials and Methods). Human f_u,microsome values were dependent on the model compounds. For example, although FK1052, FK480, nicardipine, and nilvadipine were highly bound to microsome with free fraction values ranging from 0.112 to 0.443, zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. f_u,microsome of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL_{int,in vitro} with f_u,microsome approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL_{int,in vitro} with f_u,microsome became smaller than unity (0.05–0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem, corrections of CL_{int,in vitro} with f_u,microsome corrections did not change the human scaling factor values significantly. Consequently, the scaling factor for zolpidem and omeprazole remained 4.2- to 5.1-fold and 3.1- to 5.3-fold, respectively.

**Discussion**

In the present study, we investigated the quantitative prediction of human hepatic metabolic clearance from in vitro experiments using liver microsomes focusing on P450 metabolism. The values of CL_{int,in vitro} and CL_{int,in vitro} for each model compound were compared in rats and/or dogs, and humans. As a result, 1) scaling factor values (CL_{int,in vitro}/CL_{int,in vitro}) were similar in the different animal species; 2) scaling factor values were different in each compound; 3) successful predictions of human CL_{int,in vitro} were obtained by considering animal scaling factor; and 4) use of human CL_{int,in vitro} corrected with animal scaling factor gave good predictions of CL_{rat} and E_H in humans. Namely, the empirical prediction method is a simple one of incorporating additional information (which is compound specific)
from animal studies and is based on the assumption that any in vitro-in vivo difference seen in humans is also apparent in animals to approximately the same degree.

In a conventional method, $CL_{int,in\text{ vitro}}$ is obtained from $K_m$ and $V_{max}$, which are estimated by measuring the production of metabolites over a wide range of drug concentrations. On the other hand, $CL_{int,in\text{ vitro}}$ in the proposed method is obtained from substrate disappearance rate at a single drug concentration. From comparison of these methods, advantages of the proposed method are raised as follows: 1) simple to conduct; 2) can be done for many compounds; 3) metabolites do not need to be known; 4) can be easily done without radiolabel; and 5) can yield enzyme kinetic data based on the disap-
appearance of parent compounds. On the contrary, disadvantages of the proposed method are as follows: 1) it is difficult to measure very low CL_{int,in vitro} values; 2) does not get individual metabolite information; 3) and does not obtain \( K_m \) and \( V_{max} \) parameters. Recent studies have also calculated CL_{int,in vitro} from substrate disappearance (Lave et al., 1997; Obach, 1999).

In this study, we assumed that extrahepatic clearances could be negligible. Recently, it has been reported that the first-pass metabolism in human small intestine is not negligible for some drugs, such as cyclosporine, which is metabolized mainly by CYP3A4 (Benet et al., 1996). Of the model compounds, FK480 (in house data), zolpidem (Pichard et al., 1995), nicardipine (Guengerich et al., 1991), nilvadipine (in house data), and diltiazem (Sutton et al., 1997) are metabolized mainly by CYP3A4. Human CL_{int,in vivo} of these compounds were calculated from the CL_{oral} after oral administration. Nevertheless, the CL_{int,in vivo} values predicted from human CL_{int,in vitro} with animal scaling factor consideration were comparable with the observed values (Fig. 4). From this result, although the possibility of intestinal metabolism of the model compounds cannot be completely excluded, it may be reasonable to consider the metabolism of these compounds mainly in the liver for predicting CL_{int,in vivo}. In the future, we would evaluate in vitro-in vivo scaling for the model compounds obviously metabolized in small intestine.

When CL_{int,in vivo} was calculated from in vivo clearance data, or when CL_{H} and E_{H} were calculated from CL_{int,in vitro} three frequent mathematical models (the well stirred, parallel-tube, and dispersion models) were used. Although there were a few drugs of which the human scaling factor values of all mathematical models were close to unity (nicardipine, diazepam, and diltiazem), the values for some drugs (FK1052, FK480, zolpidem, and omeprazole) were 3.1- to 26.6-fold (Table 3), resulting in CL_{int,in vivo} values larger than the CL_{int,in vitro} values. These findings suggest that the conventional prediction method, which directly applies CL_{int,in vitro} into the mathematical models, cannot always predict in vivo clearance for all compounds. By contrast, the proposed method, considering the scaling factor, yielded more accurate prediction of human CL_{int,in vivo} that was mostly within 2-fold of actual values (Fig. 4).

- ○, human f_{E} \cdot CL_{int,in vitro} corrected by dog scaling factor. The solid lines represent the simulated curves based on the mathematical models.
The use of hepatic microsomes to predict in vivo CL\text{H} requires acceptance of some assumptions (Obach, 1999). First, oxidative metabolism predominates over other metabolic routes, such as direct conjugation, reduction, hydrolysis, etc. Second, rates of metabolism measured using animal and human microsomes in vitro are truly reflective of these exist in vivo. It has been reported that diltiazem is metabolized in part by hepatic microsomal esterase in rats (LeBoeuf and Bélanger, 1987). Therefore, the CL_{int, in vitro} of microsomal esterase was estimated in conditions where no NADPH-generating system was included in the incubation mixture. As a result, the CL_{int, in vitro} of microsomal esterase represented approximately 30% of the CL_{int, in vitro} observed in the presence of NADPH-generating system in rats, whereas the CL_{int, in vitro} of microsomal esterase in dogs and humans were hardly observed (data not shown). Even for diltiazem, scaling factor values were similar among the different species (Table 3), suggesting that the CL_{int, in vitro} of microsomal esterase to clarify the validity of the consideration. Third, the substrate concentration used (1 μM in this study) is well below the apparent K\text{m}. It may be necessary to confirm this assumption. For example, for only FK480, 3.5- to 5.4-fold differences in scaling factor between animals and humans were observed (Fig. 3). It may be accounted for by the possibility that the animal CL_{int, in vitro} could be seriously underestimated because of the lower K\text{m} value at 1 μM. However, the CL_{int, in vitro} at several concentrations below 1 μM were similar to that at 1 μM in animals and humans (data not shown). Consequently, it was considered that the CL_{int, in vitro} at 1 μM was under linear condition.

$$\text{CL}_{int, in vivo} = \text{CL}_{oral} \cdot K_{H}$$

The solid line is the simulated curve using eqs. 6 to 8, based on the well stirred model. The dotted line is the simulated curve using eqs. 6, 7, and 9, based on the parallel-tube model. The broken line is the simulated curve using eqs. 6, 7, and 10 to 13, based on the dispersion model.

Presently, it is not clear why each compound has a intrinsic scaling factor. However, there are two possible reasons below. First, f_{u, microsome} in the reaction mixture may have an influence on the CL_{int, in vitro} value. Obach (1999) has examined f_{u, microsome} of model compounds and the potential impact that such binding has on the prediction of in vivo clearance from CL_{int, in vitro} for these compounds. Those results showed that incorporation of f_{u, microsome} generally yielded more accurate predictions of human clearance. In the same way, we have evaluated f_{u, microsome} of the model compounds and the change of the scaling factor values when correcting with f_{u, microsome}. However, CL_{int, in vitro} when by correcting with f_{u, microsome}, were not in agreement with the CL_{int, in vivo} for some compounds; the scaling factor values for FK1052, zolpidem, and omeprazole were several-fold, and the scaling factor values for nicardipine were much smaller than unity (Table 5). This suggests that the scaling factor different from unity might not be due only to the drug binding to liver microsomes. The second reason may be related to some assumptions of the mathematical models below: 1) the distribution of drug into the liver is assumed to be perfusion-rate limited, and diffusion of drug into hepatocytes is rapid and not subject to any diffusional barriers; 2) it is assumed that only the free (unbound to macromolecules in blood) drug crosses the cell membrane and subsequently occupies the enzyme site; and 3) a homogeneous distribution of drug-metabolizing enzymes within the liver acinus is adopted (Houston and Carlile, 1997). If any assumptions are incorrect, the discrepancies between CL_{int, in vivo} and CL_{int, in vitro} would be observed.
titative prediction of human hepatic clearance from in vitro experiments, focusing on P450 metabolism with eight model compounds. Successful predictions of human hepatic clearance were obtained by use of the human CYP\textsubscript{rat,in vitro}. Corrected with animal scaling factors, which are the ratios of CYP\textsubscript{rat,in vitro} to CYP\textsubscript{rat,in vitro}. This method would provide more reliable prediction of human hepatic clearance and be useful in drug discovery.
