ABSTRACT:

We investigated the quantitative prediction of human hepatic metabolic clearance from in vitro experiments focusing on cytochrome P450 metabolism with eight model compounds, FK1052, FK480, zolpidem, omeprazole, nicardipine, nilvadipine, diazepam, and diliazem. For the compounds, in vivo human hepatic extraction ratios ranged widely from 0.03 to 0.87. In vitro and in vivo hepatic intrinsic clearance (CLint) values for each compound were measured and calculated in rats and/or dogs and humans. CLint,in vitro was determined from a substrate disappearance rate at 1 μM in hepatic microsomes, which was a useful method. CLint,in vivo was calculated from in vivo pharmacokinetic data using three frequent mathematical models (the well stirred, parallel-tube, and dispersion models). The human scaling factor values (CLint,in vivo/CLint,in vitro) showed marked difference among the model compounds (0.3-26.6-fold). On the other hand, although the predictability of CLint,in vivo from in vitro data was good overall, most of the animal scaling factors were within 2-fold of the values in humans, suggesting that scaling factor values were similar in the different animal species. When human CLint,in vitro values were compared with the actual CLint,in vivo correlation was not necessarily good. By contrast, using human CLint,in vitro corrected with the rat and/or dog scaling factors yielded better predictions of CLint,in vivo that were mostly within 2-fold of the actual values. Furthermore, successful predictions of human CLoral and hepatic extraction ratio (Eh) were obtained by use of the human CLint,in vitro corrected with animal scaling factors. The new variant method is a simple one, incorporating additional information from animal studies and providing a more reliable prediction of human hepatic clearance.

In recent years, the process of drug discovery and development has become an increasingly time-consuming and costly endeavor. Much of the time and cost are expended on generating data that support the efficacy and safety profiles of the drug. Safe and efficient drug candidates must therefore be selected before clinical trials.

On the other hand, there is growing awareness of the key roles that pharmacokinetics and drug metabolism play as determinants of in vivo action. In these situations, early pharmacokinetic investigation plays an increasingly important role in the optimization and selection of drug candidates. In particular, it is important to predict human hepatic metabolic clearance because many drugs are eliminated from the body by hepatic metabolism. For predicting hepatic clearance, theoretical aspects of in vitro/in vivo scaling, based on a physiological model and clearance concepts, have been developed (Rane et al., 1977; Lin et al., 1982; Roberts and Rowland, 1986; Wilkinson, 1987). Application of this method has been successful in predicting in vivo hepatic clearance in rats for many drugs metabolized by P4501 from in vitro metabolism data using rat liver microsomes and isolated hepatocytes (Sugiyama et al., 1988; Houston, 1994). Since human liver samples have become more readily available, it would also be very useful to predict in vivo from in vitro data in humans. However, there has been relatively limited application of this approach (Hoener, 1994; Iwatsubo et al., 1997b), and there have been many failed attempts at predicting human hepatic clearance. For example, Iwatsubo et al. (1997a) reported a comparison of CLoral and CLint,in vitro for 25 metabolic reactions in humans from literature data. According to the report, although CLoral and CLint,in vitro generally exhibited a positive correlation with CLoral more than a 3-fold difference was observed in CLint,in vitro for about 50% of the 25 metabolic reactions. Houston and Carlile (1997) also compared CLint,in vitro obtained from in vitro experiments using rat liver microsomes with CLint,in vivo for 28 drugs metabolized by P450. Although the predictability of CLoral from in vitro data was good overall, the results of some of the drugs tended to be low estimates. To improve the predictions of human hepatic clearance, a few investigators have described new methods and approaches. For example, Lave et al. (1997) have proposed the allometric scaling techniques combined with in vitro data. Obach (1999) has
Clearances of model compounds are determined by hepatic P450 metabolism.

• Extrahepatic clearances are assumed to be negligible

• In vivo pharmacokinetic parameters in rats and/or dogs, and humans are reported

• Absorption rates are good with no species difference

Although it has been reported that diltiazem is metabolized in part by liver microsomal esterase in rats (LeBoeuf and Grech-Bélanger, 1987), the compound was examined for reference.

Hepatic Microsomes. Liver specimens from adult male Sprague-Dawley rats (250–270 g, n = 3; Charles River Japan, Inc., Yokohama, Japan) and adult male dogs (9.5–10 kg, n = 3; Japan Laboratory Animals, Inc., Tokyo, Japan) were rinsed and homogenized with ice-cold 1.15% KCl. These pooled microsomes were prepared by differential centrifugation, and the 105,000g pellet was rinsed and resuspended in 1.15% KCl. Pooled human microsomes were obtained from Human Biologics International (Scottsdale, AZ). The pooled human microsomes were prepared from 15 individual liver donors that were selected on the basis of having average activities for the major P450 isozymes (1A2, 2A6, 2B6, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A11). Each suspension was divided into aliquots, frozen, and stored at −80°C until use.

In Vitro Metabolism in Microsomes. In vitro experiments. The time courses of the unchanged model compounds in microsomes were obtained. Each compound was incubated with a reaction mixture (500 μl) consisting of animal or human liver microsomal protein and NADPH-generating system (2 mM NADP+, 10 mM glucose-6-phosphate, 0.4 U/ml glucose-6-phosphate dehydrogenase, and 5 mM MgCl2) in the presence of 100 mM potassium phosphate buffer (pH 7.4). After preincubation at 37°C for 5 min, enzyme reactions were initiated by adding 5 μl of model compound solution in methanol. The final concentration of each model compound used was 1 μM. The microsomal concentrations used were 0.2 mg/ml (nicardipine, nilvadipine, and diltiazem), 0.5 mg/ml (FK1052, zolpidem, omeprazole, and diazepam), and 1.0 mg/ml (FK480). After incubation at 37°C for various time periods, the reactions of FK1052, FK480, omeprazole, zolpidem, and diazepam were terminated by the addition of 500 μl of acetonitrile. The reactions of diazepam and nilvadipine were terminated by adding 500 μl of methanol and 3 ml of ethyl acetate, respectively. After stopping the metabolic reactions, the reaction mixtures of FK1052, FK480, omeprazole, zolpidem, nicardipine, diltiazem, and diazepam were centrifuged at 10,000 g for 5 min, and an aliquot of the supernatant was injected on an HPLC for measuring the unchanged compound concentration. The reactions of nilvadipine were processed by extraction. The organic fraction was evaporated under N2, and the residue was reconstituted in the mobile phase (see below) for HPLC analysis.

Determination of unchanged model compound concentrations. An LC module I plus (Millipore Co., Milford, MA) was used. The column for the analysis was an Inertsil ODS-3 (5 μm, 150 × 4.6 mm) GL Science, Inc., Tokyo, Japan). The flow rate was 1.0 ml/min. The mobile phase and detection wavelength for the analysis of each model compound was as follows: FK1052, mobile phase: buffer A (5 mM phosphate buffer, pH 7.2)/CH3CN (50:50), detection: UV 224 nm; FK480, mobile phase: buffer A/CH3CN (40:60), detection: UV 295 nm; Omeprazole, mobile phase: buffer A/CH3CN (35:65), detection: UV 234 nm; Zolpidem, mobile phase: buffer A/CH3CN (55:45), detection: UV 230 nm; Diltiazem, mobile phase: buffer A/CH3CN (45:55), detection: UV 265 nm; Diazepam, mobile phase: buffer A/CH3CN (50:50), detection: UV 254 nm; and FK480, mobile phase: buffer A/CH3CN (40:60), detection: UV 224 nm.

All assay methods showed the concentration range of 0.1 to 2 μM. Reproducibility was evaluated by performing five replicate analyses of microsomal samples containing 0.1, 0.5, and 1 μM compound, respectively. The coefficient of variation was less than 10%, and the actual concentration of the compounds ranged from 88 to 112.1%. All assay methods thus provide good accuracy and precision.

Calculation of $C_{\text{int,in vitro}}$ and $C_{\text{int,in vivo}}$. Values were calculated from the substrate disappearance rate in hepatic microsomes as follows. If substrate disappearance can be assumed to follow a first-order reaction, the unchanged drug profile as a function of time [C(t)] is described as follows:

$$C(t) = C_0 \cdot e^{-k \cdot t}$$

where $C_0$ is initial concentration of the compound, and $k_e$ is the disappearance rate constant of unchanged drug (per minute).

Furthermore, initial metabolic rate ($V_0$) per unit milligram of microsomal protein ($\mu$mol/min/mg microsomal protein) is described by eq. 2.

$$V_0 = k_e \cdot C_0 / P_{MS}$$  \hspace{2cm} (2)

where $P_{MS}$ is the microsomal protein concentration (mg/ml).

On the other hand, from the Michaelis-Menten equation, $V_0$ is described by eq. 3.

$$V_0 = V_{max} \cdot C_0 / (K_m + C_0)$$  \hspace{2cm} (3)

If the substrate concentration used in the experiments (1 $\mu$M) is below the $K_m$ for the P450-mediated reactions, the drug concentration may be assumed to be much smaller than $K_m$ ($K_m \gg C_0$). Thus, $V_0$ can be expressed by eq. 4.

$$V_0 = V_{max} / K_m \cdot C_0$$  \hspace{2cm} (4)

Consequently,

$$CL_{int,in vivo} = V_{max} / K_m = V_0 / C_0$$  \hspace{2cm} (5)

$CL_{int,in vivo}$ was thus calculated by eq. 5 based on the time course of unchanged drug concentrations by least square regression. The $CL_{opt,in vitro}$ values expressed per milligram of microsomal protein calculated from the in vitro metabolism experiments were expressed per kilogram of body weight by taking the microsomal protein content per gram liver and the liver weight per kilogram of body weight shown in Table 1 into consideration.

In Vivo Data. Sources of pharmacokinetic data. In vivo clearance under linear conditions, $f_u$ and $R_B$ data, were obtained from in house and literature. Taking the mean value of body weight in the literature or a body weight of 250 g, 10 kg, and 70 kg for rats, dogs and humans, respectively. The fraction value was converted so that it was expressed per kilogram of body weight, this in vivo clearance value was not expressed per kilogram of body weight, this $CL_{int,in vivo}$ for omeprazole in dogs was calculated from eqs. 7 to 13 by use of the $CL_{eq}$ value, where $CL_{eq}$ is equal to $CL_{int,R_B}$.

$E_H$ were calculated from eq. 14.

$$E_H = 1 - F_H = CL_d/Q_H$$  \hspace{2cm} (14)

Prediction of Human $CL_{int,in vitro}$ $CL_{oral}$ and $E_H$. Estimation of scaling factor. Values of scaling factor were estimated from the following equation:

$$Scaling \ factor = CL_{int,in vivo} / CL_{int,in vitro}$$  \hspace{2cm} (15)

Prediction of human $CL_{int,in vivo}$. Human $CL_{int,in vivo}$ were predicted based on human $CL_{int,in vitro}$ using the following two methods: 1) disregarding animal scaling factor; $CL_{int,in vivo}$ = human $CL_{int,in vitro}$  \hspace{2cm} (16)

2) including animal scaling factor:

$$Predicted \ human \ CL_{int,in vivo} = human \ CL_{opt,in vitro} \cdot animal \ scaling \ factor$$  \hspace{2cm} (17)

For these $CL_{int,in vivo}$ predictions, success was assessed by the geometric mean of the ratio of predicted and actual values (Obach, 1999). Thus:

$$Average \ fold \ error = 10^{\log(average \ predicted \ value) / u}$$  \hspace{2cm} (18)

Prediction of in vivo human $CL_{oral}$ and $E_P$. In vivo human $CL_{oral}$ and $E_P$ were predicted using eqs. 6 to 14, based on the human $CL_{int,in vitro}$ corrected with animal scaling factor.

Binding of Model Compounds to Microsomes. Determination of $f_{a,microsome}$. Model compounds (final concentration, 1 $\mu$M) were mixed with liver microsomes (at protein concentrations used for the respective metabolic incubations) in 100 mM phosphate buffer (pH 7.4) containing 10 mM glucose-6-phosphate, 0.4 U/ml glucose-6-phosphate dehydrogenase, and 5 mM MgCl$_2$. The mixtures (1.2 ml) were delivered to one side of a dialysis cell containing a preconditioned dialysis membrane (molecular weight cut off, 10 kDa) (Dain-ippou Pharmaceutical Co., Ltd., Osaka, Japan). To the other side of the membrane was delivered 1.2 ml of the phosphate buffer containing glucose-6-phosphate and MgCl$_2$. The cells were sealed, and the apparatus was incubated at 37°C for 4 h. After an incubation period, the microsome and buffer samples were removed and analyzed by HPLC. The HPLC conditions were the same as described above. The unbound fraction was calculated from the following:

$$f_{a,microsome} = \frac{unchanged \ compound \ concentration \ in \ buffer \ side}{unchanged \ compound \ concentration \ in \ microsome \ side}$$  \hspace{2cm} (19)

Calculation of $CL_{int,in vivo}$ and the scaling factor. By incorporating the correction with the unbound fraction in the microsomal incubation mixture, $CL_{int,in vivo}$ is defined as (Iwatsubo et al., 1997a):

$$CL_{int,in vivo} = CL_{int,in vitro} / f_{a,microsome}$$  \hspace{2cm} (20)

The value of scaling factor, which is the ratio of $CL_{int,in vivo}$ to $CL_{int,in vitro}$ was calculated from eq. 15.
Results

In Vivo Pharmacokinetic Data of Model Compounds. In vivo pharmacokinetic data for the model compounds are summarized in Table 2. F_s values were high, in the range of 0.7 to 1.0. The values of unbound fraction in plasma (or serum) (f_u) were relatively low for all compounds ranging from the highest value for diltiazem (f_u: rat, 0.184; dog, 0.298; human, 0.22) to the lowest value for FK480 (f_u: rat, 0.01). species differences were also observed in CL int,in vitro for the model compounds. In vitro for the model compounds showed that the linear log concentration declines so that the metabolite accounted for a minor portion of the unchanged drug profile in microsomes. The unchanged drug profiles at 1 h after dosing were close to the observed E_H for all compounds. The metabolic profiles of human scaling factor, which are the ratios of CL int,in vivo obtained from in vivo pharmacokinetic data to CL int,in vitro. The human scaling factor consideration were 3 to 4. By contrast, the predictability was substantially improved with the geometric mean accuracy value of 86%. Furthermore, human in vivo CL int,in vitro values corrected both with and without animal scaling factor are plotted versus actual CL int,in vitro values calculated using the mathematical models in Fig. 4. Without animal scaling factor consideration, only two (the well stirred model) or three (the parallel-tube and the dispersion models) of eight prediction values were within 2-fold of the actual CL int,in vitro, resulting in a large underestimation for most of the compounds. By contrast, using human CL int,in vitro corrected with rat and/or dog scaling factor, 9 (the parallel-tube model) or 10 (the well stirred and the dispersion models) of 13 prediction values were within 2-fold of the actual CL int,in vitro, significantly improving the predictability of CL int,in vitro.

The geometric mean accuracy values as indices of human CL int,in vitro predictability are listed in Table 4. The value of one means perfect predictability, and the poorer becomes predictability with the larger values. The geometric mean accuracy values without animal scaling factor consideration were 3 to 4. By contrast, the predictability was substantially improved with the geometric mean accuracy value of less than 2.

Furthermore, human in vivo CL oral and E_H values were predicted from human CL int,in vitro corrected with animal scaling factor. Table 5 presents comparisons of the predicted and observed CL oral values with the observed CL oral. The CL oral values predicted using the well stirred model were in good agreement with the observed values. When CL oral was predicted using the parallel-tube and the dispersion models, good correlations were observed, with the exception of the overestimation for nilvadipine.

Figure 6 shows the relation between CL int,in vitro and in vivo E_H. The predicted E_H based on f_b · CL int,in vitro corrected with animal scaling factor was close to the observed E_H for all mathematical models. This result suggests that the human CL int,in vitro with animal scaling factor was close to the observed E_H for all mathematical models.
scaling factor consideration could give a good prediction of \(E_H\) and hepatic clearance in humans.

**Binding of Model Compounds to Microsomes.** Binding experiments were conducted in similar conditions used in in vitro microsomal metabolism studies but were conducted in the absence of NADPH so that metabolism of the compounds would not occur. Recovery of the compounds was more than 90%, except nicardipine where the recovery was about 50%. Table 5 summarizes the unbound fraction in liver microsomes, human CL\(_{\text{int, in vitro}}\), corrected with \(f_u,\text{microsome}\), and the scaling factor values. \(f_u,\text{microsome}\) of diltiazem in rats could not be estimated because this compound was metabolized by microsomal esterase (see Materials and Methods). Human \(f_u,\text{microsome}\) values were dependent on the model compounds. For example, although FK1052, FK480, nicardipine, and nilvadipine were highly bound to microsome with free fraction values ranging from 0.112 to 0.443, zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes. For FK1052, FK480, and nilvadipine, the human scaling factor values obtained by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) approached unity. However, the scaling factor for FK1052 were still 5.2- to 8.6-fold. In the case of nicardipine, these values by correcting human CL\(_{\text{int, in vitro}}\) with \(f_u,\text{microsome}\) became smaller than unity (0.05-0.1-fold). For zolpidem, omeprazole, diazepam, and diltiazem showed low binding with free fraction values ranging from 0.745 to 0.975. \(f_u,\text{microsome}\) of each compound to rat and dog liver microsomes was similar to that measured in human liver microsomes.
from animal studies and is based on the assumption that any in vitro-in vivo difference seen in humans is also apparent in animals to approximately the same degree.

In a conventional method, $CL_{int,in vitro}$ is obtained from $K_m$ and $V_{max}$, which are estimated by measuring the production of metabolites over a wide range of drug concentrations. On the other hand, $CL_{int,in vitro}$ in the proposed method is obtained from substrate disappearance rate at a single drug concentration. From comparison of these methods, advantages of the proposed method are raised as follows: 1) simple to conduct; 2) can be done for many compounds; 3) metabolites do not need to be known; 4) can be easily done without radiolabel; and 5) can yield enzyme kinetic data based on the disap-
appearance of parent compounds. On the contrary, disadvantages of the proposed method are as follows: 1) it is difficult to measure very low \( CL_{\text{int,in vitro}} \) values; 2) does not get individual metabolite information; 3) and does not obtain \( K_m \) and \( V_{\text{max}} \) parameters. Recent studies have also calculated \( CL_{\text{int,in vitro}} \) from substrate disappearance (Lave et al., 1997; Obach, 1999).

In this study, we assumed that extrahepatic clearances could be negligible. Recently, it has been reported that the first-pass metabolism in human small intestine is not negligible for some drugs, such as cyclosporine, which is metabolized mainly by CYP3A4 (Benet et al., 1996). Of the model compounds, FK480 (in house data), zolpidem (Pichard et al., 1995), nicardipine (Guengerich et al., 1991), nilvadipine (in house data), and diltiazem (Sutton et al., 1997) are metabolized mainly by CYP3A4. Human \( CL_{\text{int,in vivo}} \) of these compounds were calculated from the \( CL_{\text{oral}} \) after oral administration. Nevertheless, the \( CL_{\text{int,in vivo}} \) values predicted from human \( CL_{\text{int,in vitro}} \) with animal scaling factor consideration were comparable with the observed values (Fig. 4). From this result, although the possibility of intestinal metabolism of the model compounds cannot be completely excluded, it may be reasonable to consider the metabolism of these compounds mainly in the liver for predicting \( CL_{\text{int,in vivo}} \). In the future, we would evaluate in vitro-in vivo scaling for the model compounds obviously metabolized in small intestine.

When \( CL_{\text{int,in vivo}} \) was calculated from in vivo clearance data, or when \( CL_{\text{H}} \) and \( E_{\text{H}} \) were calculated from \( CL_{\text{int,in vitro}} \) three frequent mathematical models (the well stirred, parallel-tube, and dispersion models) were used. Although there were a few drugs of which the human scaling factor values of all mathematical models were close to unity (nicardipine, diazepam, and diltiazem), the values for some drugs (FK1052, FK480, zolpidem, and omeprazole) were 3.1- to 26.6-fold (Table 3), resulting in \( CL_{\text{int,in vivo}} \) values larger than the \( CL_{\text{int,in vitro}} \) values. These findings suggest that the conventional prediction method, which directly applies \( CL_{\text{int,in vitro}} \) into the mathematical models, cannot always predict in vivo clearance for all compounds. By contrast, the proposed method, considering the scaling factor, yielded more accurate prediction of human \( CL_{\text{int,in vivo}} \) that was mostly within 2-fold of actual values (Fig. 4).

The use of hepatic microsomes to predict in vivo CL_{H} requires acceptance of some assumptions (Obach, 1999). First, oxidative metabolism predominates over other metabolic routes, such as direct conjugation, reduction, hydrolysis, etc. Second, rates of metabolism measured using animal and human microsomes in vitro are truly reflective of these exist in vivo. It has been reported that diltiazem is metabolized in part by hepatic microsomal esterase in rats (LeBoeuf and Bélanger, 1987). Therefore, the CL_{int,in vitro} of microsomal esterase was estimated in conditions where no NADPH-generating system was included in the incubation mixture. As a result, the CL_{int,in vitro} of microsomal esterase represented approximately 30% of the CL_{int,in vitro} observed in the presence of NADPH-generating system in rats, whereas the CL_{int,in vitro} of microsomal esterase in dogs and humans were hardly observed (data not shown). Even for diltiazem, scaling factor values were similar among the different species (Table 3), suggesting that the CL_{int,in vitro} which was measured in conditions with NADPH-generating in rats, reflects the metabolic rates by both P450 and esterase. However, future studies should also focus on evaluating in vitro-in vivo scaling for the other compounds metabolized by microsomal esterase to clarify the validity of the consideration. Third, the substrate concentration used (1 mM) in this study is well below the apparent K_{m}. It may be necessary to confirm this assumption. For example, for only FK480, 3.5- to 5.4-fold differences in scaling factor between animals and humans were observed (Fig. 3). It may be accounted for by the possibility that the animal CL_{int,in vitro} could be seriously underestimated because of the lower K_{m} value at 1 μM. However, the CL_{int,in vitro} at several concentrations below 1 μM were similar to that at 1 μM in animals and humans (data not shown). Consequently, it was considered that the CL_{int,in vitro} at 1 μM was under linear condition.

CL_{int,in vitro} corrected with animal scaling factor could give a good prediction of in vivo CL_{oral} and E_{H} in humans. But, for a high-clearance drug, nilvadipine, the CL_{oral} values using the parallel-tube and dispersion models were overestimated (Fig. 5). The reason is seen in the well stirred model where CL_{oral} is in proportion to CL_{int,in vitro} whereas the parallel-tube and dispersion models give exponential correlation between CL_{int,in vivo} and CL_{oral} for high-clearance drugs (Fig. 7). As a result, the error of predicted CL_{oral} which is caused from the error of predicted CL_{int,in vivo} is magnified in the parallel-tube and dispersion models compared with the error in the well stirred model. Also, in the oral case, CL_{oral} calculated based on the parallel-tube and dispersion models was affected to some extent by Q_{p} for the high-clearance drugs, whereas CL_{oral} calculated based on the well stirred model was not affected (Iwatsubo et al., 1997a). In the case of predicting CL_{oral} for high-clearance drugs, it may be necessary to consider the selection of the mathematical models.

In conclusion, we investigated a new variant method on the quan-

titative prediction of human hepatic clearance from in vitro experiments, focusing on P450 metabolism with eight model compounds. Successful predictions of human hepatic clearance were obtained by use of the human CL_{int,in vitro} Corrected with animal scaling factors, which are the ratios of CL_{int,in vivo} to CL_{int,in vitro}. This method would provide more reliable prediction of human hepatic clearance and be useful in drug discovery.
