ABSTRACT:

Most reverse transcriptase and protease inhibitors used in highly active antiretroviral therapy for treating human immunodeficiency virus (HIV) infections exhibit poor penetration into the brain, raising the concern that the brain may be a sanctuary site for the development of resistant HIV variants. This study explores the relationship between the dose and plasma and brain concentrations of zosuquidar and the effect of this selective P-glycoprotein inhibitor on central nervous system penetration of the HIV protease inhibitor nelfinavir maintained at steady state by intravenous infusions in rats. Nelfinavir was infused (10 mg/kg/h) for up to 10 h with or without concurrent administration of an intravenous bolus dose of 2, 6, or 20 mg/kg zosuquidar given at 4 h. Brain tissue and plasma were analyzed for both drug concentrations. Brain tissue/plasma nelfinavir concentration ratios (uncorrected for the vascular contribution) increased nonlinearly with zosuquidar dose from 0.06 ± 0.03 in the absence of zosuquidar and 0.09 ± 0.02 between 2 and 6 h after 2 mg/kg zosuquidar to 0.85 ± 0.19 after 6 mg/kg and 1.58 ± 0.67 after 20 mg/kg zosuquidar. Zosuquidar brain tissue/plasma concentration ratios exhibited a similar abrupt increase from 2.8 ± 0.3 after a 2 mg/kg dose to ~15 after the 6 and 20 mg/kg doses. The apparent threshold in the plasma concentration of zosuquidar necessary to produce significant enhancement in brain uptake of nelfinavir appears to close to the plasma concentrations associated with the maximum tolerated dose reported in the literature after repeated dosing of zosuquidar in patients.

Despite the success of highly active antiretroviral therapy (HAART) in the treatment of human immunodeficiency virus (HIV)-infected patients (Carpenter et al., 2000), incomplete long-term suppression of viral replication leading to the development of drug-resistant viral strains continues to be a significant concern (Kirschner and Webb, 1997; Hirsch et al., 1998; Kepler and Perelson, 1998; Schrager and D’Souza, 1998; Winters et al., 2000; Solas et al., 2003). Most of the reverse transcriptase and protease inhibitors used in HAART exhibit poor penetration into the central nervous system (CNS) (Groothuis and Levy, 1997; Kim et al., 1998; Kravcik et al., 1999; Sawchuk and Yang, 1999; Lafeuillade et al., 2002). Consequently, the brain is particularly likely to serve as a sanctuary site for the development of resistant HIV variants (Pialoux et al., 1997; Cunningham et al., 2000; Smit et al., 2004). AIDS dementia complex is an additional neurological complication of HIV replication in the CNS, affecting approximately 20 to 30% of patients with advanced HIV infection (Brew, 1999; McArthur et al., 2003), although its incidence has declined with the advent of HAART (Husstedt et al., 2002).

HIV protease inhibitors such as nelfinavir are significantly impeded in their transport across the blood-brain barrier by P-glycoprotein, a plasma membrane protein encoded by the multidrug resistance (MDR) gene that functions as an ATP-dependent efflux transporter (Kim et al., 1998; Lee et al., 1998; van der Sandt et al., 2001; Sankatsing et al., 2004). By inhibiting P-glycoprotein, it may be possible to increase protease inhibitor levels in the brain thereby reducing the role of the brain as a sanctuary site for viral replication and limiting the incidence of AIDS dementia complex. Previous studies, including our own, have demonstrated that potent P-glycoprotein inhibitors such as GF120918 and zosuquidar (LY-335979) can significantly enhance brain concentrations of protease inhibitors (Choo et al., 2000; Edwards et al., 2002; Savolainen et al., 2002; Edwards et al., 2005) and other P-glycoprotein substrates (Karsen et al., 2002; Kemper et al., 2004).

To be therapeutically effective, P-glycoprotein inhibitors should be sufficiently potent to achieve inhibitory effects at nontoxic plasma concentrations and sufficiently selective for P-glycoprotein to minimize effects on overall drug pharmacokinetics. Zosuquidar, developed as a highly potent and selective inhibitor for P-glycoprotein (Dantzig,

ABBREVIATIONS: HAART, highly active antiretroviral therapy; HIV, human immunodeficiency virus; CNS, central nervous system; MDR, multidrug resistance; GF120918, N-(4-[2-(1,2,3,4-tetrahydro-6,7-dimethoxy-2-isoquinolinyl)ethyl]-phenyl]-9,10-dihydro-5-methoxy-9-oxo-4-acridine carboxamide; LY335979/3HCl, (2R)-anti-5-[3-[4-(10,11-difluoromethanodibenzo-suber-5-yl)piperazin-1-y]-2-hydroxypropoxy]quinoline trihydrochloride; HPLC, high-performance liquid chromatography; DMSO, dimethyl sulfoxide; BCRP, breast-cancer resistance protein; AUC, area under the curve.
Nelfinavir Injections with an i.v. Bolus of Zosuquidar. Intravenous (jugular vein) infusions of nelfinavir (target rate of 10 mg/kg/h) were administered to groups of three rats each for 6, 8, and 10 h (for zosuquidar doses of 2 and 6 mg/kg) or 6 and 8 h (for zosuquidar doses of 20 mg/kg) using a Harvard 22 syringe pump. Flow rates were adjusted for body weights, which were 264 ± 26 g (mean ± S.D.; n = 21) in the group of rats given zosuquidar at either 2 or 6 mg/kg and 283 ± 27 g (mean ± S.D.; n = 6) in the group of animals given 20 mg/kg zosuquidar. Zosuquidar (2, 6, or 20 mg/kg) was given at 4 h as an i.v. bolus into the femoral vein.

Tissue Collection and Sample Preparation. At the end of each infusion, the animals were placed under anesthesia using ketamine (1:4 ratio with saline) administered through the femoral cannula. Blood was withdrawn from the abdominal aorta into a heparinized syringe while the infusion was continued. Blood samples were centrifuged, and the plasma was removed and stored at −20°C. After the blood was drawn, the infusion was discontinued, and the brain was removed from the top of the skull within 1 to 2 min. Dissected brains were rinsed with physiological saline solution to remove any external blood. They were cut into halves and frozen immediately at −20°C.

Plasma samples for nelfinavir and zosuquidar analyses were thawed, and 2 µl of ethyl acetate-acetonitrile (90:10) and 100 µl of 0.75 M NH_4OH were added to 100 µl of plasma. The samples were vortexed for 4 min and then centrifuged for 5 min at room temperature and 3000 rpm. The supernatant was removed, and solvent was evaporated under a stream of nitrogen. A second extraction was performed with 2 µl of ethyl acetate-acetonitrile (90:10). The supernatant was added to the first dried extract, and solvent was again evaporated under a nitrogen stream. The dried extracts were resuspended in mobile phase (250 µl). pH was adjusted to ~4 with glacial acetic acid, and the samples were filtered through a Gelman nylon Acrodisc 13-mm, 0.45-µm syringe filter for HPLC analysis. Blank and spiked control plasma samples were prepared as above with no added drug and 100 µl of drug standard at varying concentrations in mobile phase, respectively.

Brain samples for nelfinavir and zosuquidar analysis were thawed and one-half of each brain was weighed and placed in a 50-ml polyethylene conical tube. The sample was mixed with 700 µl of 0.75 M NH_4OH and homogenized with a Tissue-Teator (BioSpec Products, Inc.) on high speed for 2 min. The brain homogenate was extracted with 3 µl of ethyl acetate-acetonitrile (90:10) and vortexed for 4 min. The samples were centrifuged for 5 min at room temperature and 3000 rpm. The supernatant was removed, and solvent was evaporated under a stream of nitrogen. A second extraction was performed with 3 µl of ethyl acetate-acetonitrile (90:10). The supernatant was added to the first dried extract, and again the solvent was evaporated under a nitrogen stream. The dried extracts were resuspended in mobile phase (250 µl). pH was adjusted to ~4 with glacial acetic acid, and the samples were filtered through a Gelman nylon Acrodisc 13-mm, 0.45-µm syringe filter for HPLC analysis. Blank and spiked control brain tissue samples were prepared as above with no added drug, and 100 µl of drug standard at varying concentrations in mobile phase, respectively.

HPLC Analyses. Plasma and brain concentrations were determined by reversed-phase HPLC with UV detection at 254 nm (nelfinavir) and fluorescence detection at 240 nm (zosuquidar). The modular HPLC system consisted of a Waters 2690 separations module, a Waters 996 PDA detector, and a Waters 474 fluorescence detector. The separations were achieved with a Supelcosil ABZ+Plus column (5 µm, 4.6 mm × 25 cm) at a flow rate of 0.8 ml/min. Plasma extracts were analyzed isocratically using a mobile phase consisting of 45% acetonitrile-55% ammonium acetate buffer (20 mM, pH 4.40). Brain tissue extracts were analyzed using a linear gradient from 37% acetonitrile-63% pH 7.0 ammonium acetate buffer (20 mM) to 37% acetonitrile-63% pH 7.0 ammonium acetate buffer (20 mM)-56.7% pH 3.0 ammonium acetate buffer (20 mM). The dosing solutions were analyzed after the infusions and actual infusion rates or doses were calculated. Tissue concentrations of nelfinavir and zosuquidar were then normalized, if necessary, to reflect the same dose per body weight for all animals.

Equilibrium Dialysis Experiments. The effect of zosuquidar on the free fraction of nelfinavir in rat plasma was assessed by equilibrium dialysis using 10 mm/10 ml Spectrapor Float-A-Lyzer (Spectrum Laboratories, Inc.) dialysis membrane tubes (molecular weight cutoff = 3500). Two separate sets of pooled plasma samples obtained from two to four rats were treated with 10 mM ammonium formate buffer, pH 7.40, to a concentration of 20% plasma and

et al., 1999), was selected as a clinical candidate for reversing anti-cancer drug resistance mediated by P-glycoprotein because it appeared to meet these criteria (Rubin et al., 2002). Indeed, Rubin et al. were able to demonstrate that biologically effective plasma concentrations of zosuquidar could be achieved with minimal toxicity and without significant alterations in the pharmacokinetics of doxorubicin. On the other hand, Kemper et al. (2004) concluded that the dose-limiting neurological toxicity that was observed by Rubin et al. occurs at plasma levels of zosuquidar that are insufficient to improve the penetration of paclitaxel into brain tumors by P-glycoprotein inhibition.

This study explores further the relationship between the dose of zosuquidar, its plasma and brain concentrations, and its ability to enhance CNS penetration of the HIV protease inhibitor nelfinavir during infusions to steady state in rats. We find a very steep dependence between the enhancement of brain uptake of nelfinavir and the dose and/or plasma concentration of zosuquidar suggestive of a threshold plasma concentration as suggested by Kemper et al. (2004). Enhancement in brain uptake of nelfinavir coincides with an increase in the brain/plasma concentration ratio for zosuquidar.

Materials and Methods

Chemicals. Nelfinavir free base was extracted from Viracept oral powder formulation (Pfizer, Inc., La Jolla, CA). The peak purity of each batch was determined by HPLC to be ~98 to 99%. Titration of a single batch in 90% methanol-water yielded an apparent purity based on equivalent weight of 102%. Zosuquidar (LY-335979-3HCl, (2R)-anti-5-3-[4-(10,11-difluoromethanobenzo-suber-5-yl)piperazin-1-yl]-2-hydroxypropoxyquinoline trihydrochloride) was synthesized at the University of Kentucky following procedures adapted from the literature (Suzuki et al., 1997; Kroin and Norman, 1998). Its identity was established by HPLC comparison to an authentic reference standard at Eli Lilly and Company (Indianapolis, IN). Peak purity was determined by HPLC to be 97% and titration in 90% methanol-water yielded an apparent purity based on equivalent weight of 99.5%.

Surgical Procedure and Preparation of Infusion Solutions. Female Sprague-Dawley rats were obtained from Charles River (Canada) and housed and cared for by the University of Kentucky Division of Laboratory Animal Research facilities. Animal procedures were performed using guidelines for the care and use of laboratory animals established by the University of Kentucky. Animals were anesthetized using 0.5 to 5% halothane in oxygen, to effect. Aseptic technique was used to implant catheters into the jugular and femoral veins as described by Waynforth and Flecnell (1994). Hair was clipped from the back of the neck and the appropriate vein was exposed. Using a 25-gauge needle, a hole was punctured in the vein. Silastic catheters were inserted toward the heart, tied to the vein, and anchored to the surrounding tissue using 3-0 suture. Venous cannulas were externalized at the nape of the neck. All openings were closed using small wound clips. The animals were allowed a recovery period of 24 h after surgery. The catheters were flushed with 0.3 ml of normal saline containing 500 U/ml heparin.

Nelfinavir solutions were prepared in deionized water (with 1% dimethyl sulfoxide in some cases stemming from the use of concentrated stock solutions) adjusted to pH ~2.2 (DSMO) with methanesulfonic acid. Zosuquidar solutions were prepared in 5% mannitol and adjusted to pH ~2.0 with concentrated HCl. The dosing solutions were sonicated to ensure complete dissolution and analyzed by HPLC at the end of the infusion to obtain the concentrations of solutions administered.

In Vivo Experimental Designs. Nelfinavir Only Infusions. Intravenous (jugular vein) infusions of nelfinavir (target rate of 10 mg/kg/h) were administered to groups of either two or three rats (total of five to eight per infusion time) for 2, 4, 6, 8, and 10 h using a Harvard 22 syringe pump. Flow rates ranging from 1.1 to 1.8 ml/h were based on the weight of the individual animal and theoretical dosing solution concentration. Body weights on the day of the experiment were 274 ± 34 g (mean ± S.D.; n = 34).
spiked with a concentrated solution of nelfinavir free base in DMSO to a final concentration of ~10 μg/ml. Zosuquidar in DMSO was added to half of the samples to a final concentration of ~3 μg/ml. Each tube in the set was placed in a 100-ml graduated cylinder containing a stir bar, which was filled with 10 mM ammonium formate buffer, pH 7.40, to a level equal to the level of plasma solution within the dialysis tube. Samples were stirred continuously at room temperature. Aliquots of 1 ml were removed from the plasma side and the buffer side of the membrane at 24 and 48 h.

Plasma and buffer samples (1 ml) were combined with 1 ml of 0.75 M ammonium formate buffer, pH 7.40, to a level equal to the level of plasma solution within the dialysis tube. Samples were stirred continuously at room temperature. Aliquots of 1 ml were removed from the plasma side and the buffer side of the membrane at 24 and 48 h.

**Intracellular Drug Accumulation.** The influence of P-glycoprotein and breast cancer resistance protein (BCRP) overexpression on cell uptake of zosuquidar was assessed in L-MDR1 cells, which overexpress P-glycoprotein, and Saso2 cells engineered to overexpress BCRP (Schinkel et al., 1993; Wierdl et al., 2003). The pig kidney cell line LLC-PK1 and Saso2 cells transfected with pCDNA3 vector plasmid served as controls. Cells were seeded at 7 × 10^4 cells/ml. Culture medium contained 10% fetal bovine serum, 2 mM L-glutamine, 1 mM sodium pyruvate, and 1% penicillin-streptomycin. When 70-90% confluent, cells were transferred to 6-well plates and grown to 100% confluency in medium without serum. Zosuquidar (Sigma-Aldrich) was dissolved in 10 mM sodium carbonate buffer, pH 8.0, to a final concentration of 10 μg/ml, and was added to the medium when the cells reached confluence. Cells were grown to confluence for 24 h in the absence of serum. After 24 h, the medium was replaced with 1 ml of fresh medium containing 50 μg/ml zosuquidar. After 24 h, the medium was replaced with 1 ml of fresh medium immediately before the addition of 10 μl of 100× zosuquidar stock solution in DMSO to give final concentrations of 0.25, 0.5, 0.75, 1, and 10 μM zosuquidar containing 1% DMSO. After 20-min incubations, cells were washed three times with ice-cold phosphate-buffered saline containing 10% fetal bovine serum, and 200 μl of 0.75 M NH₄OH was added. Samples were rocked approximately 20 min to allow time for cell lysis, and 100 μl of this crude extract was removed and placed in a clean glass tube for extraction following the HPLC methods outlined above. The remaining sample was stored at –20°C in siliconized Eppendorf tubes for protein determination. Protein assay was carried out using a BCA Protein Assay Kit (Pierce Chemical).

**Results**

Linearity in the HPLC response versus drug concentration was demonstrated over the range of 0.1 to 50 μg/ml for both nelfinavir and zosuquidar, corresponding to the approximate range of concentrations in the diluted (plasma) or concentrated (brain) HPLC samples injected. Intraday coefficients of variation (mean ± S.D.) were 4.2 ± 1.2 and 2.7% ± 0.7% for nelfinavir and zosuquidar, respectively. Drug recoveries from spiked plasma samples were 90.2 ± 8.1 and 89.7 ± 8.7% for nelfinavir and zosuquidar, respectively, whereas drug recoveries from spiked brain tissue were 93.8 ± 14.6 and 94.6 ± 11.6% for nelfinavir and zosuquidar, respectively. Assays for the spiked brain and plasma samples over a range of 0.9 to 15 μg/ml for nelfinavir and 1 to 16 μg/ml for zosuquidar showed good linearity between the concentrations found and concentrations added [r² values were 0.9623 (nelfinavir, brain), 0.9871 (nelfinavir, plasma), 0.9740 (zosuquidar, brain), and 0.9935 (zosuquidar, plasma)].

Displayed in Table 1 are the mean tissue concentrations of nelfinavir and zosuquidar along with standard deviations and number of determinations at each time point and zosuquidar dose. These data were the source for Figs. 1 through 4.

**Nelfinavir Plasma and Brain Tissue Concentrations in the Absence of P-glycoprotein Inhibition.** Figure 1 demonstrates that steady-state plasma concentrations of nelfinavir were attained within the first 4 h of infusion, representing three to four half-lives. The mean steady-state plasma concentration was 12.4 μg/ml. From the infusion rate and mean steady-state concentration, the clearance of nelfinavir at steady state is estimated to be 1.24 l/h/kg.

Brain concentrations of nelfinavir appeared to have attained steady state with respect to plasma concentrations at the first sampling time although the concentrations achieved were significantly lower than the corresponding plasma concentrations (Table 1). Brain tissue concentrations were very low in comparison with the plasma concentrations, with an average brain/plasma concentration ratio of only 0.06 ± 0.03. Previously we estimated that the vascular content in the rat brain accounted for approximately 2% of the total brain tissue volume (Savolainen et al., 2002). Concentrations in brain parenchyma can therefore be estimated using the equation Cparenchyma = C_br - V_p/C_p, where Cparenchyma is the parenchymal brain concentration after correction for the vascular contribution, C_br is the overall drug concentration in the brain, V_p is the vascular content of the brain (≈ 0.02),

*aDifferences in nelfinavir ratios at each zosuquidar dose versus no zosuquidar were tested for significance using a one-way analysis of variance with covariate (time): N.S., not significant; ***P < 0.001.

*bDifferences in zosuquidar ratios at the 6 and 20 mg/kg zosuquidar doses versus the 2 mg/kg zosuquidar dose were tested for significance using a one-way analysis of variance with covariate (time): N.S., not significant at P < 0.05; ***P < 0.001.
and $C_p$ is the drug concentration in plasma. The brain parenchyma/plasma concentration ratio for nelfinavir after this correction was $0.037 \pm 0.027$.

**Zosuquidar Plasma and Brain Tissue Concentrations.** Plasma and brain tissue concentrations of zosuquidar after doses of 2, 6, and 20 mg/kg are listed in Table 1 and displayed graphically in Fig. 2 versus the nelfinavir infusion time. Zosuquidar was administered to these animals as an i.v. bolus 4 h after the start of the nelfinavir infusions. Although the number of time points collected was not sufficient to enable the determination of most pharmacokinetic parameters, we used the areas under the curve versus time curves between 6 and 8 h (AUC$_{6-8\,h}$) to assess the influence of zosuquidar dose on the plasma and brain concentrations because data for these time points were available at all doses. A plot of plasma AUC$_{6-8\,h}$ versus zosuquidar dose (see lower curve, Fig. 4) was linear ($r^2 = 0.9867$), indicating no effect of concentration of this P-glycoprotein inhibitor on its own plasma clearance.

An examination of the brain tissue concentrations versus either the dose of zosuquidar administered or plasma concentrations reveals a dramatic elevation in the brain tissue/plasma concentration ratio at the higher doses (6 and 20 mg/kg) of zosuquidar. As shown in Table 1, brain/plasma ratios increased from $2.8 \pm 0.3$ after a 2 mg/kg dose to $\sim15$ after the 6 or 20 mg/kg doses. This abrupt increase in brain uptake of zosuquidar with an increase in dose of $>2$ mg/kg is also evident in the plot (Fig. 4) of AUC$_{6-8\,h}$ for the brain tissue concentrations of zosuquidar versus dose in comparison to the AUC$_{6-8\,h}$ for the plasma zosuquidar concentrations versus dose.

**Effect of Zosuquidar on Plasma and Brain Concentrations of Nelfinavir.** Table 1 indicates that zosuquidar administration had no observable effect on the plasma concentrations of nelfinavir. This is also illustrated graphically in Fig. 4 by the approximately constant AUC$_{6-8\,h}$ for nelfinavir plasma concentrations with increasing doses of zosuquidar.

Zosuquidar enhances the brain uptake of nelfinavir in a dose-dependent manner, as illustrated in Table 1 and Fig. 3. Brain tissue/plasma nelfinavir concentration ratios increased from $0.06 \pm 0.03$ in the absence of zosuquidar administration and $0.09 \pm 0.02$ between 2 and 6 h after a 2 mg/kg intravenous dose of zosuquidar to $0.85 \pm 0.19$ after 6 and $1.58 \pm 0.67$ after 20 mg/kg zosuquidar. The existence of an apparent threshold concentration of zosuquidar for significant enhancement of nelfinavir uptake into brain tissue is illustrated in Fig. 4 where tissue AUC$_{6-8\,h}$ values are plotted versus dose. The zosuquidar plasma concentration at this threshold appears to be $\sim300$ to 400 ng/ml, although insufficient data are available to determine this value precisely.

**Effect of Zosuquidar on Plasma Protein Binding.** Nelfinavir is extensively bound to plasma proteins, exhibiting a high affinity for $\alpha_1$-acid glycoprotein and a relatively low affinity for human serum albumin (Schon et al., 2003). Herforth et al. (2002) reported the free fractions of nelfinavir in human plasma to be 0.41, 0.43, and 0.41% at initial nelfinavir plasma concentrations of 1, 2, and 3 µg/ml, respectively.

In the present study, the free fraction of nelfinavir was determined by equilibrium dialysis in two separate samples of pooled rat plasma at equilibration times of 24 and 48 h. The analyte concentrations in the diluted plasma declined from their initial values of $\sim10$ µg (nelfinavir)/ml and $\sim3$ µg (zosuquidar)/ml to $\sim2$ µg (nelfinavir)/ml and $\sim0.9$ µg (zosuquidar)/ml at 24 h and $\sim1.4$ µg (nelfinavir)/ml and $\sim0.5$ µg (zosuquidar)/ml at 48 h due primarily to slow drug uptake into the dialysis membrane. Membrane uptake had no apparent effect on the
free fraction of nelfinavir determined at 24 and 48 h. Values for the free fraction of nelfinavir in 20% plasma were 0.055 ± 0.006 [(-)-zosuquidar] versus 0.051 ± 0.011 [(+)zosuquidar] and 0.021 ± 0.006 [(-)-zosuquidar] versus 0.017 ± 0.001 [(+)zosuquidar] in the two pooled plasma samples, respectively. Whereas the free fraction differed in the two sets of plasma, possibly due to variability in the levels of α1-acid glycoprotein, there was no discernible effect of zosuquidar on the binding of nelfinavir to plasma proteins at these concentrations. The free fraction of zosuquidar could not be quantified in one set of pooled plasma samples, whereas a value of 0.0022 ± 0.0004 was obtained in the other set, indicating that zosuquidar is >99% bound in 20% rat plasma and more extensively protein bound than nelfinavir. Additional studies are underway to explore the dependence of zosuquidar’s plasma protein binding on its concentration in plasma.

Zosuquidar Intracellular Accumulation in P-glycoprotein- and BCRP-Expressing Cell Lines. To determine whether zosuquidar is transported by P-glycoprotein or BCRP, we examined its intracellular accumulation in cells overexpressing P-glycoprotein and BCRP in comparison to cell lines that were not transfected. Cells were incubated for 20 min with increasing zosuquidar concentrations as indicated in Fig. 5. The intracellular concentration of zosuquidar was measured using HPLC and normalized to total protein content in the cell lysate. No change was observed in the intracellular levels of zosuquidar in P-glycoprotein- or BCRP-expressing cells, suggesting that this molecule is not being effectively transported by these two efflux pumps.

Discussion

The time-to-steady state results presented in Fig. 1 are consistent with the previous finding by Shetty et al. (1996), who determined that the elimination half-life for nelfinavir after its i.v. administration in rats at doses ranging from 25 to 50 mg/kg varies from 1.1 to 1.4 h depending on dose. The steady-state plasma concentration obtained in this study, 12.4 μg/ml, is in good agreement with that reported in our previous study after an 8-h infusion at the same rate (Savolainen et al., 2002) but higher than that reported by Edwards et al. (2005). Also, the clearance estimate from the steady-state data in Fig. 1 is in reasonable agreement with the data of Shetty et al. (1996), who found that clearance in rats after intravenous bolus doses of nelfinavir was dose-dependent, varying from 3.61 l/h/kg at 25 mg/kg to 1.63 l/h/kg at 50 mg/kg.

Choo et al. (2000) reported a brain/plasma concentration ratio of 0.06 ± 0.02 in mice 2 h after an i.v. injection (50 mg/kg) of nelfinavir, uncorrected for the vascular contribution, which is in good agreement with the mean of our uncorrected ratios listed in Table 1 (0.06 ± 0.03). Shetty et al. (1996) found a brain/plasma concentration ratio of 0.068 (uncorrected for the vascular contribution) for nelfinavir in rats 4 h after an oral dose of 50 mg/kg, which also agrees well with our data. The brain parenchyma/plasma concentration ratio for nelfinavir after correcting for the vascular contribution was 0.037 ± 0.027, in reasonable agreement with the value of 0.022 ± 0.015 reported previously (Savolainen et al., 2002). Thus, all studies in rodents have confirmed limited brain uptake of nelfinavir.

Several studies have demonstrated that the P-glycoprotein efflux transporter is largely responsible for the reduced nelfinavir concentrations in brain tissue. Kim et al. (1998) found that the ratio of brain concentrations of nelfinavir in mdr1a−/− mice increased by 36.3-fold relative to mdr1a+/+ mice, whereas plasma concentrations were increased only modestly (1.26-fold). Salama et al. (2005) examined the disposition of nelfinavir in the brain and other tissues in P-glycoprotein–competent mdr1a/b+ mice versus P-glycoprotein double-knockout mdr1a/b−/− mice. Nelfinavir concentrations in brain tissue increased 16.1-fold in double-knockout mice 2 h after intravenous administration of nelfinavir (10 mg/kg), whereas plasma concentrations were unaffected by P-glycoprotein status.

Whereas zosuquidar plasma concentrations (Table 1; Fig. 2) and AUC values (Table 1; Fig. 4) increased approximately linearly with increasing zosuquidar dose, brain concentrations (Table 1; Fig. 2) and brain AUC values (Table 1; Fig. 4) exhibited more pronounced increases above a zosuquidar dose of 2 mg/kg. Thus, brain/plasma zosuquidar concentration ratios increased from 2.8 ± 0.3 after a 2 mg/kg dose to ~15 after the 6 or 20 mg/kg doses. Dramatic increases in zosuquidar brain tissue/plasma concentration ratios at the higher doses (6 and 20 mg/kg) of zosuquidar might be expected if zosuquidar were a substrate for P-glycoprotein as well as a P-glycoprotein inhibitor, as it would inhibit its own efflux. However, Dantzig et al. (1999) concluded that zosuquidar is not itself a substrate for P-glycoprotein based on cell uptake/efflux data and monolayer transport data. Studies reported herein examining zosuquidar uptake/efflux in cells overexpressing P-glycoprotein and BCRP in comparison to cells not expressing these transporters also suggest that zosuquidar efflux is not effectively achieved by P-glycoprotein or BCRP.

Studies of the binding of nelfinavir to plasma proteins in the presence and absence of zosuquidar showed no effect of zosuquidar on nelfinavir’s protein binding at the concentrations used, suggesting that the effects of zosuquidar are related to its activity as a P-glycoprotein inhibitor. However, the elevated zosuquidar brain/plasma concentration ratios with increasing zosuquidar dose could reflect changes in protein binding due to saturation with increasing dose. Preliminary evidence generated in this study suggests that zosuquidar is >99% protein bound in rat plasma.

Zosuquidar administration had no observable effect on the plasma concentrations of nelfinavir, in agreement with the findings of Choo.
et al. (2000), who reported no effect of zosuquidar doses up to 25 mg/kg on plasma concentrations of nelfinavir. We previously demonstrated that the potent but less selective P-glycoprotein inhibitor GF120918 had no influence on plasma concentrations of nelfinavir at an intravenous dose that produced significant P-glycoprotein inhibition (Savolainen et al., 2002), results that have been recently confirmed in mice (Salama et al., 2005). Moreover, both Salama et al. (2005) and Kim et al. (1998) demonstrated that plasma concentrations after intravenous administration of nelfinavir or other related HIV protease inhibitors were not altered in genetic P-glycoprotein knock-out mice.

The nelfinavir brain tissue/plasma concentration ratios of 0.85 ± 0.19 after 6 and 1.58 ± 0.67 after 20 mg/kg zosuquidar are comparable with those found by Choo et al. (2000) although slightly lower than the nelfinavir brain/plasma ratio (1.88) attained after a single bolus dose of GF120918 (10 mg/kg) (Savolainen et al., 2002) and also lower than the ratio of 2.3 reported in intravenous dose in mice (Salama et al., 2005). Moreover, both Salama et al. (2002) demonstrated that the potent but less selective P-glycoprotein inhibitor LY335979 for P-glycoprotein and effect on cytochrome P-450 activities. The threshold of zosuquidar is the elevated brain concentration/plasma concentration ratio above the threshold dose of zosuquidar. Thus, nelfinavir brain uptake of nelfinavir in rats due to P-glycoprotein inhibition by zosuquidar occurs at plasma concentrations of zosuquidar that exceed those found by Rubin et al. in the blood of cancer patients given the maximal tolerated dose, but species-to-species differences must be taken into account in considering the implications of these results.
