Received October 14, 2008; accepted December 23, 2008

ABSTRACT:

P-glycoprotein (P-gp) plays an important role in determining net brain uptake of fexofenadine. Initial in vivo experiments with 24-h subcutaneous osmotic minipump administration demonstrated that fexofenadine brain penetration was 48-fold higher in \( mdr1a(-/-) \) mice than in \( mdr1a(+/+) \) mice. In contrast, the P-gp efflux ratio at the blood-brain barrier (BBB) for fexofenadine was only ~4 using an in situ brain perfusion technique. Pharmacokinetic modeling based on the experimental results indicated that the apparent fexofenadine P-gp efflux ratio is time-dependent due to low passive permeability at the BBB. Fexofenadine brain penetration after terfenadine administration was ~25- to 27-fold higher than after fexofenadine administration in both \( mdr1a(+/+) \) and \( mdr1a(-/-) \) mice, consistent with P-gp-mediated efflux to fexofenadine in murine brain tissue. The fexofenadine formation rate after terfenadine in situ brain perfusion was comparable with that in a 2-h brain tissue homogenate in vitro incubation. The fexofenadine formation rate increased ~5-fold during a 2-h brain tissue homogenate incubation with hydroxy-fexofenadine, suggesting that the hydroxylation of terfenadine is the rate-limiting step in fexofenadine formation. Moreover, regional brain metabolism seems to be an important factor in terfenadine brain disposition and, consequently, fexofenadine brain exposure. Taken together, these results indicate that the fexofenadine BBB P-gp efflux ratio has been underestimated previously due to the lack of complete equilibration of fexofenadine across the blood-brain interface under typical experimental paradigms.

The blood-brain barrier (BBB) and blood-cerebrospinal fluid barrier (BCSFB) are the major interfaces and barriers between the central nervous system (CNS) and the peripheral circulation. The BBB and BCSFB are formed by a continuous layer of brain capillary endothelial cells (BBB) or epithelial cells that line the choroid plexus (BCSFB). The highly developed tight junctions and expression of numerous efflux transporters and metabolizing enzymes limit brain penetration of many endogenous compounds and therapeutic agents (Begley, 2003; Graff and Pollack, 2004).

Brain penetration can be beneficial or detrimental, depending on the target site of therapy and the potential for untoward side effects. Adequate exposure in the brain is essential for the treatment of cerebral diseases. However, brain exposure would ideally be minimized for compounds intended to treat peripheral disorders. BBB permeability, a primary determinant of substrate exposure in brain tissue, is influenced by many physicochemical properties such as molecular weight, \( pK_a \), lipophilicity, polar surface area, and the number of hydrogen bonds (Brodie et al., 1960; Liu et al., 2004). The extent of brain exposure, and thus the CNS pharmacologic or toxic effect, is determined by passive permeability, plasma and brain tissue binding, uptake or efflux transport activity, cerebrospinal fluid (CSF) bulk flow, and biotransformation in the CNS (Fenstermacher et al., 1981; Schinkel et al., 1994; Kalvass and Maurer, 2002; Liu and Chen, 2005; Kalvass et al., 2007a). Accurate prediction of CNS penetration is difficult because of these complex mechanisms and parameters.

In a recent study, nonspecific protein binding (i.e., capacity-limited binding to proteins other than the target receptor) in brain tissue and plasma was first used to predict in vivo CNS drug penetration (Kalvass and Maurer, 2002). These predictions were based in part on the assumption that, when compounds distribute between brain and blood solely by passive diffusion, the unbound brain and plasma concentrations are equal at distribution equilibrium. Under these conditions, the brain-to-plasma concentration ratio (brain partition coefficient; \( K_{p,brain} \)) is simply a function of the relative plasma and tissue unbound fractions \( K_{p,brain} = f_{u,plasma}/f_{u,brain} \). For many compounds that are subject to P-glycoprotein (P-gp)-mediated efflux at the BBB, brain

ABBREVIATIONS: BBB, blood-brain barrier; BCSFB, blood-cerebrospinal fluid barrier; CNS, central nervous system; CSF, cerebrospinal fluid; ER, efflux ratio; P-gp, P-glycoprotein; \( mdr1a(-/-) \), \( mdr1a(+/+) \), P-gp-deficient mice; P-gp-competent mice; P450, cytochrome P450; HPLC/MS/MS, high-performance liquid chromatography/tandem mass spectrometry; PS, surface product; ANOVA, analysis of variance; \( Cl_{passive} \), passive permeability between blood and brain compartments; \( Cl_{eff} \), P-gp-mediated efflux clearance.
penetration has been predicted successfully based on this approach as modified to account for the P-gp-mediated efflux activity (Summerfield et al., 2006; Kalvass et al., 2007a).

Non-sedating antihistamines represent an interesting class of compounds because the lack of a sedative effect is primarily due to exclusion from the brain at the blood-brain interface. Fexofenadine, for example, has been identified as a substrate of P-gp in Caco-2 cells and MDR1-overexpressing LLC-PK1 cells (Cvetkovic et al., 1999; Petri et al., 2004). P-gp subsequently was demonstrated to decrease intestinal absorption and brain exposure of fexofenadine by comparing wild-type mice with mdr1a/1b(−/−) animals (Tahara et al., 2005).

The extent of fexofenadine brain penetration in normal rats and mice is minimal (Mahar Doan et al., 2004; Tahara et al., 2005). In contrast, terfenadine enters the brain rapidly (Mahar Doan et al., 2004; Obradovic et al., 2007). Terfenadine is metabolized to hydroxylterfenadine and then to the active metabolite fexofenadine by hepatic CYP3A4 in human (Ling et al., 1995; Markham and Wagstaff, 1998). Metabolic enzymes such as cytochrome P450s (P450s) are also expressed in the human and rodent brain (Strobel et al., 2001; Miksys and Tyndale, 2002; Meyer et al., 2007). Brain P450s play an important role in local metabolism of endogenous compounds and xenobiotics, although brain P450s is only approximately 1 to 10% of liver content and not likely to influence the overall metabolism of the body. Mouse CYP3A11 and CYP3A13, the counterpart of human CYP3A4, were responsible for 6β-hydroxylation of testosterone in the brain and were induced by antiepileptic drug phenytoin treatment (Hagemeyer et al., 2003; Meyer et al., 2006). In the current study, the brain metabolism of terfenadine to fexofenadine was examined. Despite the ability to predict brain exposure of many compounds, the P-gp effect coupled with relative protein binding in blood and brain tissue can only partially explain the impaired brain penetration of fexofenadine and cetirizine (Kalvass et al., 2007a), two non-sedating antihistamines with poor permeability at the BBB. Fexofenadine brain penetration is ~35-fold overestimated based on the plasma-to-brain unbound fraction ratio assumption; this magnitude of overestimation cannot be explained by the ~3-fold P-gp effect at the BBB that has been reported (Cvetkovic et al., 1999; Tahara et al., 2005). Efflux protein(s) other than P-gp that may serve as barrier transport systems at the blood-brain interface have been proposed (Kalvass et al., 2007a). However, the functional efficiency and biologic significance of other BBB efflux transporters remain unclear, and no evidence is available to suggest an interaction between fexofenadine and other efflux transporters in brain capillary endothelium. The purpose of this study, therefore, was to understand the underlying mechanism(s) governing fexofenadine exposure in brain tissue and to re-examine P-gp-mediated fexofenadine efflux at the BBB. The central hypothesis underlying this effort is that, to date, studies have underestimated the actual BBB P-gp effect on fexofenadine brain uptake.

In the current study, the rate and extent of fexofenadine brain uptake and P-gp-mediated efflux activity at the BBB was determined using an in situ brain perfusion technique and subcutaneous osmotic minipump containing fexofenadine or terfenadine in mdr1a(+/+ ) and mdr1a(−/−) mice, and the drugs were continuously released over 24 to 168 h. A pharmacokinetic model was used to simulate the time dependence of the P-gp efflux ratio for fexofenadine and other compounds that have different passive permeability at the BBB. In addition, the influence of local metabolism on terfenadine brain disposition and consequent fexofenadine brain exposure was investigated.

**Materials and Methods**

Adult CF-1 mdr1a(+/+ ) mice and their natural mutant mdr1a(−/−) counterparts (30–40 g, 6–8 weeks of age) were purchased from Charles River Laboratories, Inc. (Wilmington, MA). All mice were maintained on a 12-h light/dark cycle with access to water and food ad libitum. All experimental procedures were performed under full anesthesia induced with ketamine/ xylazine (100/10 mg/kg, i.p.). All procedures were approved by the Institutional Animal Care and Use Committee at the University of North Carolina at Chapel Hill and were conducted in accordance with Principles with Laboratory Animal Care (NIH publication no. 85-23, revised in 1985).

14C-Diazepam (56.0 mCi/mmol) was purchased from GE Healthcare (Little Chalfont, Buckinghamshire, UK). [3H]Inulin (180.0 μCi/g) was purchased from PerkinElmer Life and Analytical Sciences (Waltham, MA). Terfenadine, fexofenadine hydrochloride, and loperamide were purchased from Sigma-Aldrich (St. Louis, MO). All of the other chemicals were commercially available and of reagent grade.

**In Situ Mouse Brain Perfusion.** The details of the in situ mouse brain perfusion have been described elsewhere (Dagenais et al., 2000). In brief, mice were anesthetized with ketamine/xylazine (100/10 mg/kg, i.p.). The perfusion buffer (Krebs-bicarbonate buffer, with 9 mM Na-glucose, pH 7.4) was oxygenated with 95% O2 and 5% CO2 and maintained at 37°C. [14C]Diazepam and [3H]Inulin were used as blood flow rate and vascular space markers, respectively. Fexofenadine or terfenadine at a final concentration of 2 μM was added to the perfusate. The right common carotid artery was cannulated with PE-10 tubing (Braintree Scientific Inc., Braintree, MA) after ligation of the external carotid artery. The cardiac ventricles were severed immediately before perfusion at 2.5 ml/min for 60 s via a syringe pump (Harvard Apparatus Inc., Holliston, MA). The experiment was terminated by decapitation and the right cerebral hemisphere was collected. Aliquots of perfusate were collected through the syringe and tubing for determination of substrate concentrations in perfusate. The perfusate and brain samples were stored at −20°C until analysis by high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS/MS). The radioactive brain samples were digested with 0.7 ml Solvable (PerkinElmer Life and Analytical Sciences) at 50°C overnight. Five milliliters of UltimaGold scintillation cocktail (PerkinElmer Life and Analytical Sciences) was added and vortex-mixed. Total radioactivity (1H and/or 14C) was determined in a Packard Tri-carb TR 1900 liquid scintillation analyser (PerkinElmer Life and Analytical Sciences).

Parameters related to the in situ brain perfusion, i.e., the cerebral vascular volume (ml/100 g brain), were calculated using the following equation:

\[
V_{\text{vasc}} = \frac{X_{\text{min}}}{C_{\text{min}}}
\]

the initial brain uptake clearance (\(C_{\text{up}}\), ml/min/100 g brain) was calculated as:

\[
C_{\text{up}} = \frac{X_{\text{brain}}T}{C_{\text{perf}}}
\]

and the apparent distributional volume (\(V_d\), ml/100 g brain) was calculated as:

\[
V_d = \frac{X_{\text{brain}}}{C_{\text{perf}}}
\]

where the amount of substrate in brain \(X_{\text{brain}}\) was corrected for blood vessel contamination by subtraction of vascular volume or a final 15-s washout with drug-free saline. The permeability surface product (PS) values were calculated based on the Crone-Renkin equation (Takasato et al., 1984):

\[
PS = -F_{pfr} \times \ln(1 - C_{\text{up}}/F_s)
\]

\(F_{pfr}\) is the perfusion flow rate measured using [14C]Diazepam as the flow rate marker.

**Mathematical Modeling and Simulations.** The time to equilibrium of brain penetration is dependent on the passive permeability, brain unbound fraction, and BBB P-gp-mediated efflux (Liu et al., 2005; Kalvass et al., 2007b). The time course of P-gp efflux ratio after continuous infusion was simulated based on a similar model structure with additional P-gp-mediated efflux activity. As the structure shows in Fig. 1, the model contains one central
(blood) compartment and one brain compartment; \( V_c \) and \( V_{br} \) are the physiologic blood and brain volumes, respectively. \( \text{CI}_p \) represents the passive permeability between blood and brain compartments, \( \text{CI}_\text{eff} \) is the P-gp-mediated efflux clearance, \( \text{Cl} \) is the systemic clearance, and \( f_{up} \) and \( f_{br} \) are plasma and brain unbound fraction, respectively. Modeling was based in part on the assumption that only unbound drug is able to cross the BBB. The passive permeability \( \text{CI}_p \) for fexofenadine is very low relative to the blood flow rate and, therefore, was assumed to be equal to the permeability coefficient \( PS \) determined by the in situ brain perfusion technique. Numerical values for these parameters were assigned as follows: \( V_c = 49 \text{ ml/kg} \) and \( V_{br} = 17 \text{ ml/kg} \) (Brown et al., 1997); \( Cl = 30 \text{ ml/min/kg} \) (Tahara et al., 2005); \( f_{up} = 0.35 \) and \( f_{br} = 0.077 \) (Kalvass et al., 2007a). The infusion rate \( k_0 \) was set to a value of 1 (unit dose). Fexofenadine PBS = 1.32 ml/min/100 g brain based on the in situ brain perfusion data. Three pairs of \( \text{CI}_p \) and \( \text{Cl}_\text{eff} \) were assigned: \( \text{CI}_p = 0.022, \text{Cl}_\text{eff} = 0.22, \text{Cl}_\text{eff} = 2.22 \text{ ml/min/kg} \); the corresponding \( \text{CI}_p = 0.54; \text{Cl}_\text{eff} = 5.39, \text{Cl}_\text{eff} = 53.90 \text{ ml/min/kg} \) for P-gp-competent mice assuming a steady-state P-gp efflux ratio of 25. \( \text{Cl}_\text{eff} = 0 \) for all P-gp-deficient mice. The P-gp efflux ratio was calculated as the ratio of brain partition coefficient in P-gp-deficient mice to P-gp-competent mice. The differential equations used for simulations were:

\[
\frac{dC}{dt} = k_0 \left( \text{Cl} + \text{CI}_p \right) C + \left( \text{CI}_p + \text{CI}_\text{eff} \right) C_0 \times f_{up} \times \text{Cl}_\text{eff}
\]

where \( C \) and \( C_0 \) are the total plasma and brain concentrations, respectively.

**In Vivo Osmotic Minipump Studies.** CF-1 mice (\( n = 3 \) per group) were anesthetized with ketamine/xylazine (100/10 mg/kg, i.p.). An Alzet osmotic minipump (release rate 1 \( \mu \)l/h over 1 week; Alzet, Palo Alto, CA) was selected. Three mice per group were used for the study. The pump was subcutaneously implanted in the back of the mice. The pump was left in place for 1 week, and the mice were sacrificed by decapitation 24 h after implantation. Additional experiments were performed to study the time course of fexofenadine P-gp efflux ratio at the BBB. To accomplish this goal, additional groups of \( mdr1a/−/− \) mice received fexofenadine hydrochloride (872 \( \mu \)g/pump) to produce plasma concentrations similar to those reported by Tahara et al. (2005). The mice were sacrificed at 24, 72, and 168 h postimplantation. Trunk blood was collected in heparinized 1.5-ml microcentrifuge tubes, and plasma was harvested after centrifugation at 3000 rpm for 5 min. The plasma and brain samples were stored at \(-20^\circ\text{C}\) until analysis by HPLC/MS/MS. The contribution of residual blood in the brain tissue to the brain partition coefficient was corrected by subtracting 1.8% from the calculated brain-to-plasma concentration ratio (Brown et al., 1997; Dagenais et al., 2000).

**Mouse Brain Metabolism.** Terfenadine brain metabolism was determined under two different experimental conditions. First, \( mdr1a/++; \) and \( mdr1a/−/− \) mouse brain hemispheres were perfused with 2 \( \mu \)M terfenadine for 1 min (\( n = 3 \), with a procedure identical to that described under *In situ Mouse Brain Perfusion*. The concentrations of fexofenadine formed in the perfused brain hemisphere were determined by HPLC/MS/MS. Second, fresh \( mdr1a/++; \) mouse brains were harvested, washed with 0.15 \( \% \) KCl, and homogenized in two volumes of phosphate buffer (pH 7.4, 1.15% KCl). Terfenadine or hydroxyl-terfenadine at a final concentration of 200 nM was incubated with brain homogenate (10 mg/ml) in the presence of potassium phosphate buffer (0.1 M, pH 7.4) and magnesium chloride (5 mM). The reaction was initiated by addition of freshly prepared NADPH (2 mM) (Ling et al., 1995; Holleran et al., 2004). After 2-h incubation at 37°C in a shaking water bath, the reaction was terminated by addition of ice-cold methanol to precipitate protein. The samples were centrifuged at 10,000g for 10 min. The supernatant was transferred to a fresh tube and evaporated under a stream of dry nitrogen. The residue was reconstituted with 50% methanol in water, and an internal standard was added. The formation of fexofenadine from terfenadine or hydroxyl-terfenadine was determined by HPLC/MS/MS.

**Sample Preparation and Quantitation.** The tissue was homogenized with addition of two volumes of distilled water after brief probe sonication. The perfusate was diluted with two volumes of methanol. A 25-\( \mu \)l aliquot of plasma or brain homogenate was transferred to an HPLC vial, and protein was precipitated with 100 \( \mu \)l of methanol containing internal standard (10 ng/ml loperaflamide) followed by a 25-\( \mu \)l aliquot of dimethyl sulfoxide. The sample was vortex-mixed and centrifuged. Standard solutions ranging from 0.5 to 5000 \( \mu \)M were prepared in a similar manner. In brief, 25 \( \mu \)l of blank plasma or brain homogenate, 100 \( \mu \)l of methanol containing internal standard, and 25 \( \mu \)l of serially diluted standard solution were mixed and centrifuged. The supernatant was analyzed by HPLC-tandem mass spectrometry (API 4000 triple quadrupole with TurboionSpray interface; Applied Biosystems/MDS Sciex, Concord, ON, Canada). Three microliters of sample solutions were injected via an autosampler (Leap, Carrboro, NC). Fexofenadine, terfenadine, terfenadine-oh, and the internal standard loperaflamide were eluted from an Aquasil C18 column (2.1 \( \times \) 50 mm, dp = 5 \( \mu \)m; Thermo Fisher Scientific, Waltham, MA) using a mobile phase gradient [A, 0.1% formic acid in water; B, 0.1% formic acid in methanol; 0–0.70-min hold at 0% B, 0.70–3.12-min linear gradient to 90% B, 3.12–4.10-min hold at 90% B, 4.10–4.20-min linear gradient to 0% B, 4.20–4.90-min hold at 0% B; solvent delivery system (Shimadzu, Kyoto, Japan); flow rate = 0.75 ml/min; 0.8–4 min directed to mass spectrometer] and were detected in positive-ion mode using multiple reaction monitoring: fexofenadine: 502.4→466.4 \( m/z \); terfenadine, 472.3→436.5 \( m/z \); terfenadine-oh, 488.3→452.5 \( m/z \); loperaflamide, 477.4→426.0 \( m/z \). All analytes were quantified with standard curves in the linear range of the relationship between detector response and analyte concentration prepared in the appropriate matrix. The lower limit of detection was 0.5 \( ng/ml \); inter- and intraday coefficients of variations were <15%.

**Statistical Analysis.** Data are reported as mean ± S.D. for 3 mice per condition. A two-tailed Student’s \( t \) test, or either a one-way or two-way analysis of variance (ANOVA), where appropriate, was used to determine the statistical significance of differences among two or more groups. The level of significance was corrected for multiple comparisons (e.g., Bonferroni test) or adjusted for unequal variance when necessary. In all cases, \( p < 0.05 \) was considered to be statistically significant.

**Results**

**In Situ Mouse Brain Perfusion.** \(^{1}H\)Inulin was used as the brain capillary space marker to measure the BBB physical integrity. \(^{1}C\)Diazepam was perfused as a marker of functional perfusate flow rate. The vascular volume was 1.69 ± 0.10 ml/100 g, and functional flow rate was 25 ± 41 ml/min/100 g brain. P-gp gene deficiency had no influence on the vascular volume or functional perfusion rate. The initial brain uptake clearance (\( \text{CI}_{\text{up}} \)) \( (\text{ml/min/100 g brain tissue}) \) of fexofenadine and terfenadine in \( mdr1a/++; \) and \( mdr1a/−/− \) mice is shown in Fig. 2. The P-gp efflux ratio, calculated as the ratio of \( \text{CI}_{\text{up}} \) in \( mdr1a/−/− \) mice to \( mdr1a/++; \) mice, was 4.4 and 1.1 for fexofenadine and terfenadine, respectively.

**Mathematical Modeling and Simulation.** Simulations were conducted with three different sets of values for \( \text{CI}_p \) and \( \text{CI}_\text{eff} \) (Fig. 3). The time course of the apparent fexofenadine P-gp efflux ratio was simulated when \( \text{CI}_p \) was equal to the actual value determined from the in situ brain perfusion experiment (1 × PS). All of the other variables were physiologic or biologic parameters (i.e., \( V_c, f_{up}, f_{br}, \) and \( f_{mdr} \)) or estimates of fexofenadine pharmacokinetic parameters (i.e., \( CI \)) obtained from the literature (Brown et al., 1997; Tahara et al., 2005;
Fig. 2. Initial brain uptake clearance (Cl_{up} ml/min/100 g) for fexofenadine and terfenadine in mdr1a(+/+) (solid bar) and mdr1a(−/−) (open bar) mice. The mouse brain hemisphere was perfused via the common carotid artery at 2.5 ml/min for 60 s. Data are presented as mean ± S.D. (n = 3). A Student’s t test was used to determine the statistical significance of P-gp effect between mdr1a(+/+) and mdr1a(−/−) mice. The asterisk (*) represents the statistical difference (p < 0.05) between mdr1a(+/+) and mdr1a(−/−) mice.

Fig. 3. Simulated P-gp efflux ratios over time for varying Cl_t and Cl_{up} (Cl_t = 2.24, Cl_{up} = 53.90; Cl_t = 0.22, Cl_{up} = 5.39; Cl_t = 0.022, Cl_{up} = 0.54; Cl_{up} = 0 for P-gp-deficient mice). The P-gp efflux ratio was calculated as the ratio of brain-to-plasma concentration ratio in mdr1a(−/−) mice to mdr1a(+/+) mice. The solid circles (○) represent fexofenadine P-gp efflux ratios determined at 24, 72, and 168 h during subcutaneous osmotic minipump administration. The open circle (□) is the P-gp efflux ratio determined at 2.5 h in Tahara et al. (2005).

Kalvass et al., 2007a). The simulations predicted that 12 h and 36 h would be required for fexofenadine to achieve 50% and 90% of the steady-state P-gp efflux ratio, respectively. When Cl_t was increased 10-fold, the time to achieve the maximum P-gp efflux ratio shortened. In contrast, when Cl_{up} was 10-fold lower than the actual experimental value obtained for fexofenadine, the P-gp efflux ratio did not plateau during the time frame of the simulation.

In Vivo Osmotic Minipump Studies. Fexofenadine brain-to-plasma concentration ratios at 24 h after administration of either fexofenadine or terfenadine in mdr1a(+/+) and mdr1a(−/−) mice are displayed in Fig. 4. Steady-state fexofenadine plasma concentrations were 28.5 ± 8.3 and 45.5 ± 3.1 nM in mdr1a(+/+) and mdr1a(−/−) mice during fexofenadine administration, respectively. During terfenadine administration, concentrations of terfenadine in plasma and brain tissue were below the limit of quantitation. However, plasma concentrations of fexofenadine derived from terfenadine were identical in mdr1a(+/+) (7.1 ± 2.8 nM) and mdr1a(−/−) (7.1 ± 1.7 nM) mice. Fexofenadine brain-to-plasma concentration ratios after 24 h of fexofenadine administration were 0.0056 ± 0.010 and 0.27 ± 0.08 in mdr1a(+/+) and mdr1a(−/−) mice, respectively. In contrast, the fexofenadine brain-to-plasma concentration ratios after 24 h of terfenadine administration were 0.14 ± 0.03 and 7.44 ± 2.12 in mdr1a(+/+) and mdr1a(−/−) mice, respectively. The fexofenadine brain-to-plasma ratios therefore were ~25- and 27-fold higher in mdr1a(+/+) and mdr1a(−/−) mice, respectively, after terfenadine administration compared with after fexofenadine administration. The calculated fexofenadine P-gp efflux ratios after fexofenadine and terfenadine administration are 48 and 55, respectively.

Fexofenadine hydrochloride at a dose of 872 μg/pump, selected to produce plasma concentrations (380–480 nM) similar to those in a previous study by Tahara et al. (2005), was administered in mdr1a(+/+) and mdr1a(−/−) mice for 24, 72, and 168 h. Plasma concentrations of fexofenadine achieved with this approach were 305 ± 74 and 836 ± 138 nM in mdr1a(+/+) and mdr1a(−/−) mice, respectively, and did not vary with time during this period. The brain-to-plasma concentration ratios of fexofenadine during prolonged continuous infusion by subcutaneous osmotic minipumps are shown in Fig. 5. The P-gp efflux ratios were 17, 23, and 25, at 24, 72, and 168 h, respectively. The calculated P-gp efflux ratio values, together with the P-gp efflux ratio at 2.5 h from Tahara et al. (2005), are shown in Fig. 3. These experimentally derived values correspond closely with the predicted values based on the mathematical simulation.

Mouse Brain Metabolism. The fexofenadine formation rate in brain tissue during in situ brain perfusion with 2 μM terfenadine for 1 min in mdr1a(+/+) and mdr1a(−/−) mice, and after 2-h incubation of 200 nM terfenadine or hydroxyl-terfenadine with whole brain tissue homogenate, is displayed in Fig. 6. The fexofenadine formation rate during 1-min terfenadine brain perfusion was 17.0 ± 3.1 and 12.0 ± 5.4 nM/min/kg brain tissue in mdr1a(+/+) and mdr1a(−/−) mice, respectively. The fexofenadine formation rate during a 2-h incubation of whole brain homogenate with terfenadine or hydroxylation-terfenadine was 12.9 ± 3.5 or 74.9 ± 11.8 nM/min/kg brain tissue, respectively.

Discussion

Lipophilicity and ionization at physiologic pH are important determinants of brain penetration (Brodie et al., 1960). Fexofenadine is ionized at physiologic pH and crosses the BBB to only a minimal extent. In contrast to preformed fexofenadine, the fexofenadine prodrug terfenadine, a very lipophilic molecule, evidenced a brain uptake that approximated perfusate flow. This very high uptake clearance was similar between mdr1a(+/+) and mdr1a(−/−) mice, even though terfenadine has been reported to be a P-gp substrate (Mahar Doan et al., 2004; Obradovic et al., 2007). The lack of a discernible P-gp effect for this substrate was consistent with the efficient unidirectional uptake of terfenadine during short-term brain perfusion.

P-gp has been reported to be involved in fexofenadine intestinal
secretion and, thus, in the systemic disposition of this compound. [\textsuperscript{14}C]Fexofenadine plasma concentrations in \textit{mdr1a} knockout mice were \(~4.6\)-fold higher than that in wild-type mice after intravenous administration (Cvetkovic et al., 1999). In the current study, fexofenadine plasma concentrations in \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice were approximately 60 to 206\% higher than in \textit{mdr1a}(+/+) mice. These observations are in contrast to a previous report by Tahara et al. (2005), which indicated that plasma concentrations of fexofenadine were similar in P-gp-competent and P-gp-deficient bile duct-cannulated mice.

P-gp also is involved in fexofenadine penetration of the BBB. The influence of P-gp on brain uptake of fexofenadine was demonstrated for the first time with the in situ brain perfusion technique, using the \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mouse model of P-gp deficiency. The P-gp effect during short-term brain perfusion (4.4-fold) was modest. In vivo administration under conditions that produce steady state provides a more sensitive approach to quantitating the BBB P-gp effect than short-term brain perfusion when substrate equilibration across the blood-brain interface is slow. Continuous infusion with a subcutaneous osmotic minipump provides useful steady-state information from a simple experimental system. This approach was used in the current study. As anticipated, the \textit{in vivo} P-gp efflux ratio exceeded that determined by the \textit{in situ} brain perfusion, which has been demonstrated experimentally in the present study and previously (Dagenais et al., 2001). The present results also are consistent with previous mathematical predictions based on a simple three-compartment model (representing plasma, endothelial cell layer, and brain) that showed ER\textsubscript{p} (in vivo P-gp efflux ratio) must be higher than ER\textsubscript{B} (in situ P-gp efflux ratio) for the same substrate and efflux transporter system (Kalvass and Pollack, 2007).

Fexofenadine brain-to-plasma concentration ratio at 24 h (i.e., during continuous minipump administration) was 25- to 27-fold higher after terfenadine administration than fexofenadine administration in both \textit{mdr1a}(+/+) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice. This difference might be due to the low permeability of fexofenadine. In the presence of such a low uptake clearance, a significantly longer period of time would be required to reach distribution equilibrium across the BBB, and so the apparent brain-to-plasma ratio at 24 h may be an under-prediction of the true equilibrium value. Indeed, this situation has been demonstrated previously by Liu et al. (2005) using a simulation approach. Alternatively, the precursor of fexofenadine, terfenadine, is permeable at the BBB. If terfenadine is metabolized in the brain after crossing the BBB, an increase in fexofenadine brain exposure, relative to administration of preformed fexofenadine, would be predicted.

To test the first possible mechanism, simulation studies were conducted in parallel with animal experiments. Mathematical modeling demonstrated that the P-gp efflux ratio must be time-dependent. Moreover, these simulations successfully predicted the P-gp efflux ratios measured at the selected experimental time points. The interpretation of the simulation results is both straightforward and logical: because it takes longer for slowly permeable compounds to equilibrate across the BBB, the experimentally determined P-gp efflux ratio will also take a longer time to reach its equilibrium (theoretically maximum) condition. Experimentally, fexofenadine was administered for a prolonged time period up to 168 h. The present results demonstrate a clear time dependence of fexofenadine P-gp efflux ratio during this time range of 24 to 168 h. The determined P-gp efflux ratio values, together with the P-gp efflux ratio of \(~3.3\) at 2.5 h taken from Tahara et al. (2005), were almost superimposable with the predicted values based on the model simulation.

To assess the influence of P-gp on fexofenadine brain exposure when fexofenadine is formed from terfenadine, versus when fexofenadine is administered directly, fexofenadine plasma concentrations must be similar between the two administration modalities. To achieve similar fexofenadine concentrations from preformed fexofenadine compared with fexofenadine concentrations after terfenadine administration, fexofenadine hydrochloride was administered via osmotic minipump at a continuous rate of 1.5 nM/h. The fexofenadine P-gp efflux ratios determined in vivo at distribution equilibrium were similar (55 versus 48), regardless of whether fexofenadine was formed from terfenadine or administered directly. The P-gp efflux ratio decreased when fexofenadine plasma concentration was \(~10\)-fold higher (305 nM) in the time course studies, consistent with at least partial saturation of the transport process.

Based on the impaired brain penetration of fexofenadine in both \textit{mdr1a}(+/+) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice at all time points after fexofenadine administration, the 25- to 27-fold increase of fexofenadine brain penetration after terfenadine administration could not be explained by simply attaining distribution equilibrium more rapidly with the prodrug. Thus, it was important to address the possibility that local metabolism of terfenadine to fexofenadine in the brain was responsible for the observed difference. Terfenadine is metabolized to hydroxyl-terfenadine then to the carboxylic acid metabolite fexofenadine, by hepatic CYP3A4 in humans. CYP3A11 and 3A13 are the

---

**FIG. 5.** Fexofenadine brain-to-plasma concentration ratio in \textit{mdr1a}(+/+) (solid bar) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) (open bar) mice at 24, 72, and 168 h after subcutaneous osmotic minipump administration of fexofenadine. Data are presented as mean \(\pm\) S.D. (\(n = 3\)). Two-way ANOVA was used to compare brain-to-plasma concentration ratios between \textit{mdr1a}(+/+) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice, and among the time points, respectively. The asterisk (*) represents a statistical difference (\(p < 0.05\)) between \textit{mdr1a}(+/+) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice. There were no differences for fexofenadine brain partition coefficients at different time points.

**FIG. 6.** The fexofenadine formation rate in the brain hemisphere after 60-s terfenadine in situ mouse brain perfusion in \textit{mdr1a}(+/+) and \textit{mdr1a}(\textunderbar{−}/\textunderbar{−}) mice, or a 2-h incubation of terfenadine (Terf) or terfenadine-OH (Terf-OH) with whole brain tissue homogenate. Data are presented as mean \(\pm\) S.D. (\(n = 3\)). One-way ANOVA statistical analysis corrected for multiple comparisons (Bonferroni test) demonstrated that fexofenadine formation rate in the brain was significantly higher when incubated with terfenadine-OH than incubation with terfenadine or 1-min terfenadine brain perfusion (*, \(p < 0.05\)).
murine counterparts of human 3A4 and are expressed in the mouse liver and brain (Hagemeyer et al., 2003; Meyer et al., 2006). After terfenadine administration, terfenadine plasma and brain concentrations were below the limit of quantitation, although fexofenadine concentrations in the plasma and brain were substantial. These observations confirm efficient metabolism of terfenadine in the mouse. Fexofenadine plasma concentrations were identical in mdr1a(+/+ and mdr1a(−/−) mice, indicating that the formation rate of fexofenadine from terfenadine did not differ between mouse strains. Terfenadine seemed to be metabolized to fexofenadine in mouse brain during a short (1 min) brain perfusion, as well as during a 2-h in vitro incubation with brain tissue homogenate (Fig. 6).

The fexofenadine formation rate in the brain during terfenadine brain perfusion was comparable between mdr1a(+/+ and mdr1a(−/−) mice, suggesting that the corresponding enzyme(s) activity in brain was not modulated by P-gp. These novel observations provided supporting evidence, consistent with the pharmacokinetic arguments, that terfenadine must be metabolized to fexofenadine both systemically and regionally in the brain. The local metabolism significantly increased fexofenadine brain exposure compared with what would be expected if fexofenadine was simply formed from terfenadine systemically.

The enzyme(s) responsible for terfenadine-to-fexofenadine bioconversion in murine brain is unknown, although it is reasonable to speculate that CYP3A11 and/or CYP3A13 may be responsible. This metabolic situation may have pharmacologic consequences. Fexofenadine is a nonsedating antihistamine, at least in part because it does not penetrate the BBB efficiently. In contrast, high-dose terfenadine administration has been associated with sedative effects (Mattila and Paakkari, 1999). It is possible that terfenadine itself is the causative agent for sedation. Alternatively, terfenadine may be inert but provides sufficient fexofenadine to the brain, via local metabolism, to allow fexofenadine to cause sedation.

Antihistamines represent an interesting pharmacologic class from the standpoint of BBB permeation and central nervous system responsivity. Fexofenadine and cetirizine are both nonsedating antihistamines caused by poor BBB permeability secondary to P-gp-mediated efflux at the BBB (Pollit et al., 2003). Hydroxyzine is sedating, as is terfenadine at high doses (Mattila and Paakkari, 1999). A comprehensive pharmacokinetic study of cetirizine after intravenous administration of cetirizine and hydroxyzine has been conducted (Chen et al., 2003). Re-examination of these published results demonstrated that the cetirizine P-gp efflux ratio was ~4.4 after administration of preformed cetirizine. However, the cetirizine P-gp efflux ratio after administration of hydroxyzine, the more permeable precursor of cetirizine, was ≥125 at 240 min. This experimentally determined efflux ratio is remarkably similar to the predicted value of 111 based on the unbound fraction of cetirizine in plasma versus brain and the intrinsic transport activity of cetirizine by P-gp (Kalvass et al., 2007a). Thus, the overall prediction of the uptake and P-gp efflux ratio after fexofenadine and terfenadine administration. The results demonstrated that P-gp is an important determinant of fexofenadine efflux at the BBB and, consequently, the presentation of fexofenadine to brain tissue. Studies to date have underestimated the actual P-gp efflux ratio of fexofenadine at the BBB because the P-gp efflux ratio is time-sensitive, and previous experiments were not sufficiently long to uncover the true efflux ratio. The present experiments also demonstrated for the first time the metabolism of terfenadine to fexofenadine in murine brain. The enzyme(s) responsible for terfenadine metabolism in the brain require further investigation. These latter results underscore the fact that enzymes in the brain or the BBB not only represent a metabolic barrier for substrate presentation to the brain, but also might activate some drugs to cause CNS responses (either therapeutic or toxic). Modulation of brain metabolic enzymes by coadministered drugs might represent a source of drug-drug interaction.
