ABSTRACT:
Cytochrome P450 (P450) protein-protein interactions have been observed with various in vitro systems. It is interesting to note that these interactions seem to be isomorph-dependent, with some combinations producing no effect and others producing increased or decreased catalytic activity. With some exceptions, most of the work to date has involved P450s from rabbit, rat, and other animal species, with few studies including human P450s. In the studies presented herein, the interactions of two key drug-metabolizing enzymes, CYP2C9 and CYP2D6, were analyzed in a purified, reconstituted enzyme system for changes in both substrate-binding affinity and rates of catalysis. In addition, an extensive study was conducted as to the “order of mixing” for the reconstituted enzyme system and the impact on the observations. CYP2D6 coinubation inhibited CYP2C9-mediated (S)-flurbiprofen metabolism in a protein concentration-dependent manner. V_max values were reduced by up to 50%, but no appreciable effect on K_m was observed. Spectral binding studies revealed a 20-fold increase in the K_S of CYP2C9 toward (S)-flurbiprofen in the presence of CYP2D6. CYP2C9 coinubcation had no effect on CYP2D6-mediated dextromethorphan O-demethylation. The order of combination of the proteins (CYP2C9, CYP2D6, and cytochrome P450 reductase) influenced the magnitude of catalysis inhibition as well as the ability of increased cytochrome P450 reductase to attenuate the change in activity. A simple model, congruent with current results and those of others, is proposed to explain oligomer formation. In summary, CYP2C9-CYP2D6 interactions can alter catalytic activity and, thus, influence in vitro-in vivo correlation predictions.

In addition to interactions with CPR and b5, P450s can also interact with each other, resulting in changes in metabolism rates (Kaminsky and Guengerich, 1985; Alston et al., 1991; Shimada et al., 1994; Cawley et al., 1995; Tan et al., 1997; Yamazaki et al., 1997; Backes et al., 1998; Backes and Cawley, 1999; Li et al., 1999; Cawley et al., 2001; Hazai and Kupfer, 2005; Kelley et al., 2005, 2006). Reconstituted expressed enzymes [human CYP2C9-CYP2C19 (Hazai and Kupfer, 2005), rabbit CYP1A2-CYP2B4 (Yamazaki et al., 1997), rabbit CYP1A2-CYP2E1 (Kelley et al., 2006), human CYP3A4-CYP1A1 (Yamazaki et al., 1997), human CYP3A4-CYP1A2 (Yamazaki et al., 1997)] mirror results from induced animals (Kaminsky and Guengerich, 1985; Cawley et al., 2001), and triple-expression systems [CYP3A4, CYP2D6, and CPR (Li et al., 1999), CYP2E1, CYP2A6, and CPR (Tan et al., 1997)] have exhibited protein-protein interactions. However, P450-P450 interactions are not universal, because studies with reconstituted enzymes (Kelley et al., 2006) or microsomes from rats (Dutton et al., 1987) did not demonstrate interactions between CYP2E1 and CYP2B4. Initial suggestions that protein-protein interactions occurred because of competition for CPR (West and Lu, 1977) were disproven in subsequent studies using saturating concentrations of CPR (Kaminsky and Guengerich, 1985). CPR activity in the form of cytochrome c was also measured to discount loss of CPR activity as a reason for the observed substrate inhibition.

Understanding and elucidating the mechanisms underlying P450-
P450 interactions are important for several reasons. First, they may affect predictions of in vivo clearance from in vitro data. Many times, these predictions are determined using expressed enzyme systems that may not contain the full complement of P450s and, thus, the potential for interactions. Second, a better understanding of P450-P450 interactions may provide insights into the organization of these proteins within the cell and their aggregation characteristics and how these features affect catalytic activity. Third, P450-P450 interactions may provide valuable insights into protein structure-function relationships and how the presence of different proteins may affect individual protein function.

Several possible mechanisms of altered P450 function resulting from these interactions have been explored. The role of ionic interactions between P450 pairs has been evaluated (Kelley et al., 2005) using high concentrations of buffer salts to disrupt possible ionic interactions of CYP2B4 and CYP1A2 and restore most of the P450 activity. Investigators also have used molecular modeling of protein-protein interactions to evaluate how proteins might interact to form heteromers that may alter activity (Backes et al., 1998; Hazai et al., 2005). However, it remains unclear whether conformational changes, altered catalytic cycle functioning, or other mechanisms are responsible for the observed changes in P450 function.

CYP2C9 comprises approximately 10% of the liver P450, whereas CYP2D6 comprises 2 to 3% but is involved in the metabolism of 30% of all drugs (Shimada et al., 1994). One to 5% of the white population has multiple copies of CYP2D6, leading to greater CYP2D6 proteins, and lower CYP2C9/CYP2D6 ratios in these individuals (Meijerman et al., 2007). In the current study we examined the consequence of CYP2C9-CYP2D6 interactions, and the resulting impact on metabolism rates. In addition, the role of CPR on these interactions was evaluated. Previous work (Gorsky and Coon, 1986) has demonstrated that order of mixing of P450 proteins with redox transfer proteins can alter the rate of metabolism, and thus the order of combination of these enzymes (CYP2C9, CYP2D6, and CPR) in a reconstituted system was also explored to evaluate what role this might play in the degree of interactions observed.

**Materials and Methods**

**Materials.** Acetonitrile, dibasic potassium phosphate, methanol, and phosphoric acid were purchased from Thermo Fisher Scientific (Waltham, MA). Dextromethorphan, dilaurylophosphatidylcholine (DLPC), levalloiphen (internal standard), NADPH, and triethanolamine were purchased from Sigma-Aldrich (St. Louis, MO). Dextromethorphan was purchased from Sigma/RBI (Natick, MA). (S)-Flurbiprofen, 4'-hydroxyflurbiprofen, and 2-fluoro-4-biphenyl acetic acid (internal standard) were gifts from the former Pharmacia, Inc. (Kalamazoo, MI). Human CYP2D6.1 and human P450 CPR were purchased from Invitrogen (Carlsbad, CA). CYP2C9.1 was expressed and purified as described previously (Locuon et al., 2006).

**Enzyme Reconstitution.** Incubations contained P450s, extruded DLPC vesicles (10 μg/incubation), CPR, and substrate. Different mixing schemes (sequential and simultaneous) of CYP2C9, CYP2D6, and CPR were explored. In the sequential mixing scheme, two components were mixed and allowed to equilibrate on ice for 5 min, followed by the addition of the third component and further equilibration on ice for 5 min. In the simultaneous mixing scheme, all three components were mixed consecutively and allowed to equilibrate for 10 min on ice. The order of mixing of the P450s was also investigated, and all experimental mixing conditions are summarized in Table 1. Once all three components had equilibrated on ice, they were reconstituted in DLPC (extruded through a 200-nm pore size membrane) and allowed to further equilibrate for 5 or 10 min in the case of sequential or simultaneous mixing, respectively. Enzyme mixtures were then added to substrate and buffer and preincubated at 37°C for 8 min before initiation of the reaction.

**Analysis of 4'-Hydroxyflurbiprofen.** 4'-Hydroxyflurbiprofen formation was quantitated exactly as described previously (Tracy et al., 2002).

**Dextromethorphan Metabolism by CYP2D6 in the Presence of CYP2C9.** Dextromethorphan (1, 2, 5, 10, 20, 50, 100, 150, and 200 μM), CYP2D6 (10 pmol/incubation), CYP2C9 (0 or 10 pmol/incubation), and CPR (20 or 40 pmol/incubation) were incubated together in 50 mM potassium phosphate buffer (pH 7.4) at 37°C. Reactions were initiated with NADPH (1 mM final concentration), and at 20-min incubation time, the reactions were terminated by adding 200 μl of 180 mg/ml 2-fluoro-4-biphenyl acetic acid (internal standard) in acetonitrile followed by 40 μl of half-strength phosphoric acid to adjust to pH −3.0 for HPLC separation. All experiments were performed three times on separate days.

**Analysis of (S)-Flurbiprofen Spectral Binding.** Difference spectra were obtained to evaluate enzyme-substrate affinity based on the alteration in heme iron spin state that occurs when active site water(s) are displaced through (S)-flurbiprofen binding. In brief, various ratios of CYP2C9 (0 and 0.5 μM concentrations) and CYP2D6 (0 and 0.5 μM concentrations) and 0.5 μg of DLPC/pmol of P450 in 50 mM potassium phosphate buffer (pH 7.4) were mixed in the sample and reference cuvettes. Increasing concentrations of (S)-flurbiprofen, dissolved in 50 mM potassium phosphate (pH 7.4) with a small amount of acetonitrile, were added to the sample cuvette (the acetonitrile concentration did not exceed 1%), and phosphate buffer was added to the reference cuvette and a 3-min equilibrium interval was allowed between readings. Spectral binding experiments were conducted on an Aminco DW2000 spectrophotometer with an Olis upgrade (Olis, Inc., Bogart, GA) set to record spectra from 340 to 500 nm wavelength with a slit width of 0.5 μm and 20 scans per datum at 1.0-nm steps. The temperature of the cell was held constant at 30°C with a FI12 compact refrigerated circulator with an external ED temperature controller (Julabo USA, Inc., Allentown, PA). The difference in absorbance between high-spin (390 nm) and low-spin (418 nm) components was calculated and plotted against the (S)-flurbiprofen concentration, and the data were fit by nonlinear regression (SigmaPlot 8.0, Systat Software, Inc., San Jose, CA) to estimate the Ks (spectral binding constant) from the titration binding curve using the following equation:

\[
\Delta A = \frac{B_{max}[S]}{K_s + [S]}
\]
Effect of CYP2D6 on CYP2C9 Metabolism of (S)-Flurbiprofen.

The effects of various amounts of coincubated CYP2D6 and CPR on the metabolism of (S)-flurbiprofen are presented in Figs. 1 and 2. Figure 1 shows the metabolism of (S)-flurbiprofen when three concentrations of CYP2D6 and 10 pmol of CPR were used in each incubation, and Fig. 2 shows the same when 20 pmol of CPR was used in each incubation. In all cases, a CYP2D6 concentration-dependent inhibition was observed, resulting in a decrease in $V_{\text{max}}$ but less change in $K_{\text{m}}$. When 2.5 or 5 pmol of CYP2D6 was preincubated with CYP2C9, significant inhibition ($p < 0.05$) was observed. Figures 3 and 4 summarize the effect of CYP2D6 on the $V_{\text{max}}$ of (S)-flurbiprofen metabolism by CYP2C9 when the order of combination of the enzymes was varied. When CYP2C9 was combined with CYP2D6 followed by the addition of CPR (SeqAdd1), a reduction in $V_{\text{max}}$ was observed (Fig. 3A). Increasing the levels of CPR did not restore the CYP2C9 activity. A similar trend was observed when CYP2C9 and CPR were initially combined and then CYP2D6 was added (SeqAdd2) (Fig. 3B). However, when CYP2D6 and CPR were initially combined, followed by the addition of CYP2C9, addition of more CPR reduced the amount of inhibition (SeqAdd3) (Fig. 3C), demonstrating that order of mixing can affect the nature of inhibition. Figure 4 depicts the inhibition of CYP2C9-mediated metabolism of (S)-flurbiprofen when CYP2C9, CYP2D6, and CPR were mixed together simultaneously and preincubated before the addition of DLPC. Figure 4A depicts the data obtained when the order of mixing was CYP2C9, then CPR, followed by CYP2D6 (Allmix1), and Fig. 4B shows data when the order of mixing was CYP2C9, then CYP2D6, followed by CPR (Allmix2). Inhibition was observed at all levels of CYP2D6, and this inhibition was significantly reduced ($p < 0.05$) by the addition of more CPR. There was no difference observed between Allmix1 and Allmix2, wherein the order of addition of CYP2D6 and CPR was reversed. In all cases, as the amount of CYP2D6 was increased, the degree of inhibition of (S)-flurbiprofen metabolism was also increased. However, at low CYP2D6/CYP2C9 ratios (0.2:1), less than 10 to 20% inhibition was observed. At the highest tested CYP2D6/CYP2C9 ratio of 1:1, the ratios of $V_{\text{max}}/V_{\text{max-control}}$ ranged from 50 to 80%. Hence, a halving of maximal velocity was observed at the highest ratio of CYP2D6/CYP2C9. The effect of saturating levels of CPR on the amount of inhibition in various mixing schemes is summarized in Table 2. Control incubations of CYP2D6 with (S)-flurbiprofen (no CYP2C9 present) demonstrated that CYP2D6 was unable to metabolize (S)-flurbiprofen to the 4'-hydroxy metabolite, and no additional peaks were noted in the chromatograms (data not shown).

Effect of CYP2D6 on CYP2C9 Metabolism of (S)-Flurbiprofen.

The presence of equimolar ratios of coincubated CYP2D6 and CPR on the metabolism of (S)-flurbiprofen is shown in Fig. 5. The $V_{\text{max}}$ values for dextromethorphan O-demethylation by CYP2D6 ranged from 0.2 to 0.4 pmol/min/pmol of CYP2D6, whereas $K_{\text{m}}$ was between 4 and 8 $\mu$M.

Spectral Binding Studies. To determine whether the protein-protein interactions between CYP2C9 and CYP2D6 resulted in an alteration in binding affinity for the substrate, P450 spectral binding...
titration studies were performed. In the presence of CYP2C9 alone (control) the spectrally determined binding affinity ($K_S$) for $(S)$-flurbiprofen was $6 \mu M$ (Fig. 6). The addition of equimolar CYP2D6 shifted the $K_S$ for $(S)$-flurbiprofen to $118 \mu M$ (Fig. 7), resulting in a decrease in binding affinity. A control binding experiment with $(S)$-flurbiprofen and CYP2D6 alone confirmed that $(S)$-flurbiprofen was not causing a spin state change in CYP2D6, suggesting that $(S)$-flurbiprofen did not bind to CYP2D6 (Fig. 8). To further confirm that $(S)$-flurbiprofen does not bind to the CYP2D6 active site, the metabolism of dextromethorphan by CYP2D6 in the presence of $(S)$-flurbiprofen was evaluated, and $(S)$-flurbiprofen had no effect on dextromethorphan metabolism by CYP2D6 (data not shown). This absence of competitive inhibition, along with the spectral binding data presented above, further reinforces that $(S)$-flurbiprofen does not enter the CYP2D6 active site, ruling out the possibility that $(S)$-flurbiprofen binding to the CYP2D6 heme contributed to the alterations in the observed binding affinity of $(S)$-flurbiprofen for CYP2C9. The 20-fold increase in $K_S$ toward $(S)$-flurbiprofen in the presence of

![Figure 2](https://example.com/fig2.png)

**Fig. 2.** Effect of CYP2D6 on $(S)$-flurbiprofen metabolism by CYP2C9 at 20 pmol of CPR/incubation. A to E represent SeqAdd1, SeqAdd2, SeqAdd3, Allmix1, and Allmix2, respectively. Data fitting for the plots are shown. For clarity, representative data from a single experiment are presented. However, all experiments were conducted in triplicate over 3 separate days, and the mean values were used for inhibition degree determination. Single-factor analysis of variance was used for statistical comparisons. OH, hydroxy.

![Figure 3](https://example.com/fig3.png)

**Fig. 3.** Effect of CYP2D6 on CYP2C9-mediated $(S)$-flurbiprofen metabolism for three levels of CYP2D6 and two levels of CPR. A to C depict the effect of CPR on the amount of inhibition for SeqAdd1, SeqAdd2, and SeqAdd3, respectively. The ratios of $V_{max}$ are significantly different ($p < 0.05$) from unity when the CYP2D6 levels are 2.5 and 5 pmol/incubation. In A and B, increasing CPR (20 pmol versus 10 pmol) did not affect the degree of inhibition. In C (SeqAdd3), a significant ($p < 0.05$) decrease in degree of inhibition was observed when CPR levels were 20 pmol and CYP2D6 was at 2.5 pmol/incubation, compared with 10 pmol of CPR. Single-factor analysis of variance was used for statistical comparisons.
CYP2D6 indicates an increased dissociation of the flurbiprofen-CYP2C9 complex when CYP2D6 is present and is consistent with the inhibitory results from the kinetic studies in the reconstituted systems.

**Discussion**

Protein-protein interactions involving cytochrome P450 proteins can affect catalytic turnover in either a positive or negative manner and consequently affect in vitro-in vivo correlations of drug disposition. Several previous studies have demonstrated either inhibition or stimulation of P450-mediated metabolism due to protein-protein interactions (Cawley et al., 1995, 2001; Yamazaki et al., 1997; Hazai and Kupfer, 2005), but others have not observed an effect (Kelley et al., 2006), suggesting that the effects may be isoform- and/or substrate-dependent in a manner that affects the rate of metabolism. In the present work, it was demonstrated that CYP2D6 coincubation with CYP2C9 results in a gene dose-dependent inhibition of CYP2C9-mediated flurbiprofen hydroxylation with no effect on $K_{m}$. This effect was not completely reversed by addition of more CPR. Furthermore, the order of mixing of the constituents had a measurable effect on the degree of inhibition noted. It is interesting to note that CYP2C9 had no effect on CYP2D6 catalytic activity. CYP2D6 expression is polymorphic, resulting in substantially different levels of expression of active protein among individuals, which may affect CYP2C9 activity in individuals and complicate in vitro-in vivo correlations.

Although some of the parameters affecting protein-protein interac-
The order of combination of the enzymes also has not been explored in a systematic manner previously. Kaminsky and Guengerich (1985) briefly evaluated the order of addition of the competing P450 after the addition of CPR, lipids, and substrate. This order of addition was found to have no influence on the amount of inhibition observed. In the current work presented here, \( K_m \) was unaffected by protein-protein interactions; however, the order of combination of enzymes also seemed to affect the rate of metabolism. In theory, reversible interactions between proteins should not be influenced by the order of addition, whereas the formation of tightly bound heteromers (quasi-irreversible interactions) would be affected by the order of mixing. In the current study this was also able to be probed by altering mixing order. Because mixing order affected the rate of metabolism in the current study, these results suggest that quasi-irreversible interactions are occurring when CYP2C9, CYP2D6, and CPR are combined.

In an attempt to explain the effects of order of addition observed in our system, a simplistic kinetic model is proposed below. The basis for the proposed model lies in the following assumptions: 1) P450s mixed together form heteromers with each other and CPR (Alston et al., 1991; Backes et al., 1998; Backes and Kelley, 2003; Hazai et al., 2005); 2) heteromer complexes retain catalytic activity (Backes et al., 1998); 3) only one P450 binding site exists on a single CPR molecule (Backes et al., 1998); and 4) additional combinations of proteins (e.g., CPR-CYP2C9-CYP2D6-CPR) can be formed but are found in lower amounts than the primary species (CYP2D6-CYP2C9-CPR) (Backes and Kelley, 2003).

The following mixing schemes represent the order of addition (only primary species presumed to be formed are shown).

1. SeqAdd1: 2C9_2D6_5mins_CPR

2C9 + 2D6→2C9-2D6

\[ \text{+CPR} \rightarrow 2C9-2D6-\text{CPR} + \text{CPR-2C9-2D6} \]

2C9 + 2D6→2C9-2D6

\[ +2[\text{CPR}] \rightarrow 2C9-2D6-\text{CPR} + \text{CPR-2C9-2D6} \]

In this mixing scheme, doubling the amount of CPR does not produce a new species, but simply more of the same two species.
Studies of P450 protein-protein interactions using either denatured or apoproteins also demonstrated inhibition of catalytic activity (Kaminsky and Guengerich, 1985), lending additional credence to the hypothesis that conformational changes occur as a result of the protein interactions. However, it must be recognized that these inactive proteins may also bind CPR, albeit to a nonproductive endpoint. Locuson et al. (2007), demonstrated that apo-b5 could stimulate CYP2C9-mediated metabolism despite its inability to provide electrons (Locuson et al., 2007). In addition, these results demonstrated that the apoprotein was not competing with the CPR for binding to the enzyme, because activity was stimulated rather than inhibited.

Cytochrome P450 2C9 has a relative large and flexible active site architecture that has been proposed to accommodate more than one substrate molecule simultaneously (Hummel et al., 2003), whereas it has been reported that CYP2D6 is characterized by a smaller active site volume and accepts primarily basic nitrogen and planar aromatic ring substrates (Rowland et al., 2006). This larger active site volume and flexibility of CYP2C9 compared with CYP2D6 may explain in part the differential inhibition of CYP2C9 if conformational changes induced by P450-P450 interactions are critical to the observed effects. The change in CYP2C9 affinity (K_a) for substrate observed in the current studies is consistent with a conformational change in the active site architecture.

The current studies demonstrate in vitro interactions between two important human P450 enzymes (CYP2C9 and CYP2D6), resulting in a differential reduction in catalytic activity. The order of combining these enzymes yielded unexpectedly different results that could be explained by a simple kinetic model consistent with previous modeling results and, thus, providing indirect evidence for the formation of CYP2C9-CYP2D6 heteromers that further complex with CPR to form a reactive entity that results in altered metabolism rates and the potential to confound in vitro-in vivo correlations.

References

Gorsky LD and Coon MJ (1986) Effects of conditions of reconstitution with cytochrome b5 on the lipid matrix (DLPc) when two enzymes are coincubated in reconstituted systems and microsomal systems (Kaminsky and Guengerich, 1985; Cawley et al., 2001) have also exhibited inhibition and activation, suggesting that differences in incorporation into lipids provides an incomplete explanation for the observed changes. It has been suggested that in vivo the ratio of total P450/CPR is 20:1, whereas in reconstituted systems the ratio used is 1:2 (Estabrook et al., 1971). What role the ratio (in vivo versus in vitro) of P450 to its redox partner CPR plays in this interaction is unclear. However, two studies (Kaminsky and Guengerich, 1985; Cawley et al., 2001) did observe a protein-protein interaction in microsomes from rats treated in vivo with enzyme-specific enzyme inducers, suggesting that the observations are not an artifact of the in vitro system. The other P450 redox partner, cytochrome b5, also can alter the catalytic activity and kinetic profile of P450 metabolism through mechanisms independent of provision of electrons (Jushchyshyn et al., 2005; Locuson et al., 2007), purportedly via conformational changes in the P450 induced by cytochrome b5. For simplicity, cytochrome b5 was omitted from the experiments described herein, but it should be recognized that the situation may be even more complicated than currently presented.

Several explanations have been put forth to explain, at least in part, P450 protein-protein interactions, including the role of ionic bonds between P450 proteins. Kelley et al. (2005) used high concentrations of buffer salts to eliminate any ionic interactions between CYP1A2-CYP2B4 and were able to regain most of the activity that had been diminished by the purported interactions. However, circular dichroism studies have demonstrated conformational changes in proteins at high salt concentrations (Yun et al., 1996), rendering the aforementioned studies somewhat ambiguous. It is possible that ionic interactions play a role in P450-P450 interactions but additional work in this area is needed.
CYP2C19 to catalyze methoxychlor demethylation in human liver microsomes. Drug Metab Dispos 33:157–164.
