THE 2010 BERNARD B. BRODIE AWARD LECTURE

Structure and Function of Cytochromes P450 2B: From Mechanism-Based Inactivators to X-Ray Crystal Structures and Back

James R. Halpert
Skaggs School of Pharmacy and Pharmaceutical Sciences, University of California, San Diego, La Jolla, California

Received March 23, 2011; accepted April 18, 2011

ABSTRACT:

This article reviews work from the author dating back to 1978 and focuses on the structural basis of cytochrome P450 (P450) function using available contemporary techniques. Early studies used mechanism-based inactivators that bound to the protein moiety of hepatic P450s to try to localize the active site. Subsequent studies used cDNA cloning, heterologous expression, site-directed mutagenesis, and homology modeling based on multiple bacterial P450 X-ray crystal structures to predict the active sites of CYP2B enzymes with considerable accuracy. Breakthroughs in engineering and expression of mammalian P450s enabled us to determine our first X-ray crystal structure of ligand-free rabbit CYP2B4. To date, we have solved 11 CYP2B4 and three human CYP2B6 structures, which represent four significantly different conformations.

Introduction

It is a great honor to have been chosen as the recipient of the 2010 Bernard B. Brodie Award in Drug Metabolism. I thank the American Society for Pharmacology and Experimental Therapeutics for their recognition of the research done in my laboratory. I am indebted to the many graduate students, postdoctoral fellows, research faculty, visiting scientists, staff, and undergraduates who worked with me over the past 30 years. Finally, I am grateful to the many collaborators around the world who made research possible that could never have been done by one research group alone. Being a member of the “P450 superfamily” of scientists has been a tremendous experience and an opportunity that has enriched both my scientific and personal life. I am especially fortunate to have been able to train a number of important problems with scientific rigor, and recognizing just how much guidance to provide to bring out the best in me. In working with my own trainees, I have always tried to combine the best of what I learned from my own mentors. Bob Neal’s idea in 1978 was to use mechanism-based inactivators (MBIs) to label the active sites of P450s. At that time, P450 was just a colored contaminant in the preparations of rabbit liver epoxide hydrolase that I was trying to purify (Halpert et al., 1979). It was not until I arrived in the laboratory of Dr. Robert A. Neal1 at the Center for Environmental Toxicology at Vanderbilt University in 1978 that P450 became the focus of my research. I will always be grateful to David, Magnus, and Bob for instilling in me a love for science, emphasizing the importance of tackling important problems with scientific rigor, and recognizing just how much guidance to provide to bring out the best in me. In working with my own trainees, I have always tried to combine the best of what I learned from my own mentors.

The plasticity of CYP2B4 has been confirmed by deuterium exchange mass spectrometry and is substantiated by molecular dynamics simulations. In addition to major movement of secondary structure elements, more subtle reorientation of active site side chains, especially Phe206, Phe297, and Glu301, contributes to the ability of CYP2B enzymes to bind various ligands. Isothermal titration calorimetry has proven to be a useful tool for studying the thermodynamics of ligand binding to CYP2B4 and CYP2B6, and NMR has enabled study of ligand binding orientation in solution as an adjunct to X-ray crystallography. A major challenge remains to harness the power of the various approaches to facilitate prediction of CYP2B specificity and inhibition.

1 I would like to express my sorrow at the recent passing of Bob Neal after a long, courageous battle with cancer. Bob was truly an outstanding scientist, leader, mentor, and gentleman.

ABBREVIATIONS: P450, cytochrome P450; MBI, mechanism-based inactivator; WM, Wistar-Munich; BBT, N-benzyl-1-aminobenzotriazole; SRS, substrate recognition site; 4-CPI, 4-(4-chlorophenyl)imidazolide; PR, plastic region; 1-CPI, 1-(4-chlorophenyl)imidazolide; 1-PBI, 1-biphenyl-4-methyl-1H-imidazolide; RMSD, root mean square deviation; ITC, isothermal titration calorimetry; DXMS, deuterium exchange mass spectrometry; MD, molecular dynamics; BP, 4-benzylpyridine; NBP, 4-(4-nitrobenzyl)pyridine; TBPA, tert-butylphenylacetylene; M1, 7-hydroxyticlopidine; M2, 2-oxidepidine; M3, 5-(2-chlorobenzyl)thieno[3,2-c]pyridin-5-ium metabolite; M4, 5-(2-chlorobenzyl)thieno[3,2-c]pyridin-5-ium metabolite; M5, ticlopidine N-oxide; TSOD, ticlopidine S-oxide dimer; M6, dimerization product of ticlopidine S-oxide.
some pioneering studies with parathion (Kamataki and Neal, 1976), suggesting that it might be one of few agents capable of labeling the protein moiety of P450s. Working with highly purified fractions of what we now call CYP2B1, I found that although parathion did indeed modify P450 protein, the mechanism of inactivation was exceedingly complex and unlikely to help elucidate the nature of the active site (Halpert et al., 1980). Dr. Chris Chengelis, another postdoctoral fellow in the laboratory, showed me an article suggesting that the antibiotic chloramphenicol might be more suitable than parathion for labeling CYP2B1 protein. That fortuitous interaction with Chris led to a series of studies involving enzyme purification, labeling, site-directed mutagenesis, homology modeling, X-ray crystallography, and solution biophysics that have kept my research going for the past 30 years. This work and recently culminated in a collaborative project with Dr. Paul Hollenberg on X-ray crystal structures of CYP2B4 with a metabolite of tert-butylphenylacetylene bound to Thr302. Thus, the work on P450 has truly been a journey from MBIs to X-ray crystal structures and back.

Mechanism-Based Inactivation of Hepatic Cytochromes P450 by Chloramphenicol and Analogs. A key initial finding was that CYP2B1 could be inactivated by chloramphenicol with no loss of P450 detectable as the reduced CO-complex or of heme detectable as pyridine hemochromogen. The inactivation was accompanied by the covalent binding of 1.5 nmol of metabolite per mol of P450 (Halpert and Neal, 1980). In a subsequent study that Bob graciously let me publish as the sole author, I showed that there were two classes of adducts of chloramphenicol and CYP2B1, including N,N-chloramphenicol oxamyl lysine. To our knowledge, this was the first clear identification of an adduct of a reactive intermediate of a xenobiotic and a P450 (Halpert, 1981). In later studies performed while I was a research faculty member in Jan-Åke Gustafsson’s department in Hudinge, Sweden, we demonstrated the formation of this adduct after in vivo administration of chloramphenicol to phenobarbital-treated rats (Halpert et al., 1983). This finding set the stage for my first publication as an independent faculty member in the College of Pharmacy at the University of Arizona, in which CYP2B1 isolated from chloramphenicol and phenobarbital-treated rats was found to be deficient in the ability to accept electrons from NADPH-cytochrome P450 reductase (Halpert et al., 1985b). Accordingly, chloramphenicol was not suitable for identifying amino acid residues involved in ligand binding.

Concomitant with the mechanistic studies, we began to investigate the isoform selectivity of chloramphenicol in rats, in what became a very fruitful series of collaborative studies with Dr. Larry Kaminsky (Halpert et al., 1985a). Of the eight rat liver P450 enzymes known at the time, in vivo administration of chloramphenicol was found to be selective for labeling CYP2B1 protein. That fortuitous interaction with Chris led to a series of studies involving enzyme purification, labeling, site-directed mutagenesis, homology modeling, X-ray crystallography, and solution biophysics that have kept my research going for the past 30 years. This work and recently culminated in a collaborative project with Dr. Paul Hollenberg on X-ray crystal structures of CYP2B4 with a metabolite of tert-butylphenylacetylene bound to Thr302. Thus, the work on P450 has truly been a journey from MBIs to X-ray crystal structures and back.

Initial Studies of the Structural Basis of CYP2B Substrate Specificity. In the early 1990’s, our focus broadened to encompass the structural basis of substrate specificity of CYP2B enzymes from rat, rabbit, and dog using hybrid enzymes and site-directed mutagenesis (He et al., 1992, 1994, 1996; Luo et al., 1994; Szklarz et al., 1996). These studies capitalized on the substrate recognition site (SRS) model created by Gotoh (1992). A key element of our approach was the analysis of results with CYP2B homology models based on three bacterial P450 structures (Szklarz et al., 1995, 1996). Despite the low sequence identity between the bacterial P450 and CYP2B enzymes, our approach allowed us to identify most of the active site residues involved in substrate oxidation (Szklarz and Halpert, 1997; Domanski and Halpert, 2001) long before our first X-ray crystal structure of a CYP2B-ligand complex (Scott et al., 2004). Subsequently, homology models of CYP2B1, CYP2B4, and CYP2B5 were used to rationalize selective inhibition by phenylmethylsulfoxide (Spatzenegger et al., 2001), and a combined pharmacophore and protein model of CYP2B6 was constructed to analyze substrate oxidation by this human enzyme (Wang and Halpert, 2002).

CYP2B4 Open Ligand-Free Structure. The first X-ray crystal structures of rabbit CYP2C5 were huge breakthroughs in the study of mammalian P450s (Cosme and Johnson, 2000; Williams et al., 2000; Wester et al., 2003a, b). To obtain sufficient amounts of high-quality CYP2C5 for crystallization trials, both N-terminal and internal modifications and mutations were necessary. However, it was not clear whether these modifications were necessary or sufficient to crystallize other microsomal P450s. Fortunately, expression of similarly truncated and N-terminally modified CYP2B1, CYP2B4, and CYP2B11 without further internal modifications was found to yield large amounts of catalytically active CYP2Bs with increased solubility, which were suitable for structural and functional analysis (Scott et al., 2001). These findings enabled the first crystallization of rabbit CYP2B4 (Table 1) (Scott et al., 2003). Although analyses of ligand-bound and ligand-free structures of CYP2C5 (Wester et al., 2003a, b) indicated that P450s are flexible enzymes, the wide-open structure of CYP2B4 (Fig. 1B) showed a drastic rearrangement of what were later termed “plastic regions” (Zhao et al., 2006). This reorganization of secondary structural elements creates a large substrate access cleft through movement of the F-G cassette region, which comprises helices F, F’, G’, and G on one side of the enzyme and the B’/C loop and C helix on the other (Scott et al., 2003). In contrast, regions on the proximal side of the enzyme (helices E, J, K, and L) remain relatively unchanged compared with other P450 structures. In this structure, the open conformation is stabilized through formation of a homodimer where residues of helices F’ and G’ partially fill the active site of a symmetry-related molecule, and the imidazole moiety of His226 coordinates the sixth ligand position of the heme iron of the opposite chain. Subsequently, all CYP2B4 structures have been determined with an H226Y mutant to prevent this dimerization.

Analysis of the open structure of CYP2B4 showed that active site residues on the N helix (Ser294, Phe297, Ala298, and Thr302) and those near β1...4 (Leu362, Ile363, and Val367) were in close proximity to the heme. However, numerous other active site residues identified by site-directed mutagenesis and comparison to the CYP2C5 structures (Ile101, Ile114, Phe115, Phe206, Ile209, Val477, and Gly478) were located far from the heme and each other. In this CYP2B4 protein conformation, it would be impossible for a substrate bound in the active site to make contact with all of these residues, implying that some
structural rearrangement would be necessary upon substrate binding for these residues to move into proximity of the ligand. Crystallographic studies of a CYP2B4-ligand complex were expected to reveal the conformational change associated with the closure of the active site.

Structural Studies of CYP2B4 and Imidazoles. To map the structural response of CYP2B4 to the presence of ligands, crystallographic studies of a series of chemically uniform imidazole-based inhibitors were undertaken. Correlating structural information to solution behavior of the enzyme and using these data to predict new ligands was also a major goal of this effort. The approaches used in these studies span a range of techniques, all designed to complement one another to provide a clearer picture of the relationship between enzyme structure and function.

4-(4-Chlorophenyl)imidazole. The 4-(4-chlorophenyl)imidazole (4-CPI) (Fig. 1A) complex of CYP2B4 adopts a closed conformation (Table 1) (Scott et al., 2004) as predicted. Portions of the enzyme that formed the open cleft in the ligand-free structure have moved toward each other to close the active site around the small inhibitor (Fig. 1C). The B’ helix and N terminus of the I helix move toward each other, which places the B’ helix near the G helix. Helices F, F’, G, G and their associated loops, which form what is known as the F-G cassette, move to interact with the A helix and β1 sheet at the N terminus of the enzyme, helix B’ and the B’/C loop, the N terminus of the I helix, and the β4 sheet, thus capping the active site. The F-G cassette forms the lid of the active site, and interactions between residues of helices B’ and G appear to play a key role in closing the active site.

4-CPI was found to make contact with 11 CYP2B4 residues (Ile101, Val104, Ile114, Phe115, Phe297, Ala298, Glu301, Thr302, Ile363, Val367, and Val477) that are all within 5 Å of the bound inhibitor. This list is in agreement with those identified previously as active site residues by site-directed mutagenesis studies of CYP2B1 (Domanski et al., 2001; Domanski and Halpert, 2001; Honma et al., 2005). The CYP2B4 active site, which packs tightly around the relatively small 4-CPI (178.6 Da) inhibitor, would probably have to expand to some degree to accommodate CYP2B substrates, which are generally larger molecules.

---

**Fig. 1.** Structural plasticity of CYP2B enzymes observed by X-ray crystallography. A, the structural diversity of CYP2B ligands and substrates is indicated by the variability of size, shape, and chemical functionality of compounds bound in CYP2B4 and CYP2B6 structures. In binding these ligands, CYP2B enzymes have been observed to adopt four markedly different conformations. B, in the absence of ligand, CYP2B4 is able to adopt an open conformation, with a U-shaped active site cleft. C, the most populated CYP2B form is the closed conformation, which corresponds to CYP2B4 complexes of 4-CPI, 1-CPI, ticlopidine, and clopidogrel, the closed tBPA-modified and closed ligand-free CYP2B4 structures, and the CYP2B6 complexes of 4-CPI, BP, and NBP. D, CYP2B4 has also been observed in a second open conformation in complex with bifonazole that is distinct from the open ligand-free structure. The open tBPA-modified CYP2B4 structure also resembles this conformation. E, the 1-PBI complex of CYP2B4 adopts a conformation that is intermediate to the closed and bifonazole-bound structures. Flexible helices of note have been labeled in B to E.
Bifonazole. To obtain a structure of CYP2B4 in an intermediate conformation between the ligand-free and 4-CPI bound structures, the enzyme was crystalized with the larger, branched, imidazole inhibitor bifonazole (310.4 Da) (Fig. 1A) (Zhao et al., 2006). With a wide-open active site (Fig. 1D), the resulting structure (Table 1) is actually expanded even more than the ligand-free structure. Ten residues (Ser128, Met132, Val292, Leu295, Phe296, Ala298, Gly301, Thr302, and Ile363) were found within 5 Å of the inhibitor. Only four of them (Ala298, Glu301, Thr302, and Ile363) also make contact with 4-CPI in that structure. These changes are caused by concerted movement of several secondary structural elements, most notably the B’/C loop and C helix, F-G cassette, and N terminus of the I helix. Rather than forming the typical B’/C loop structure, which contains helix B’, residues 100 to 115 move upward toward the N terminus of the enzyme in a fully extended loop with no helix. The C helix is also pulled upward, where it moves closer to the N terminus of the I helix, which bent ~15° to expand the ligand binding pocket. The F helix is approximately 1.5 turns shorter in the structure and the F/F’ loop is much longer. The length of this loop allows the F’ helix to move upward and away from the active site. Helix G is also pushed away from the protein core, resulting in no contact with the ligand. In addition, to protect the hydrophobic F’ helix, CYP2B4-bifonazole forms a dimer in the crystal, where the F-G regions of one molecule insert into the active site of a symmetry-related molecule and vice versa. This is thought to occur to protect hydrophobic regions exposed during crystallization. However, these portions of the protein are likely buried in the membrane in vivo.

After careful analysis of the CYP2B4 ligand-free structure as well as the 4-CPI and bifonazole complexes, it was found that approximately half of the protein structure is conserved regardless of the presence or absence of ligand or the size of any bound ligand. The regions correspond to the N-terminal proline-rich region, the C-terminal half of helix A, helix B, the C-terminal half of helix I, helices J through L, and β-sheets 1, 2, and 3. These regions form the protein core, including most of the secondary structural elements involved in heme binding. Many secondary structural elements on the proximal side of the protein are also conserved, consistent with their role in binding of electron transfer partners NADPH-cytochrome P450 reductase and cytochrome b₅. However, residues in five regions were subject to structural variability and defined as plastic regions (PR). PR1 (residues 39–57) comprises a loop preceding helix A as well as the N-terminal half of helix A. PR2 (residues 101–140) includes helix B’, the B’/C loop, helix C, and the C/D loop. PR3 (residues 177–188) comprises the C-terminal half of helix E and the following loop. The largest plastic region, PR4 (residues 203–298), includes the C-terminal half of helix F through the N-terminal half of helix I. The smallest plastic region, PR5 (residues 474–480), forms the β4 hairpin in the CYP2B4-4-CPI structure. These plastic regions of CYP2B4 undergo correlated conformational changes in response to ligand binding (Fig. 1), enabling the enzyme to dramatically reshape its active site without perturbing the overall P450 fold.

1-(4-Chlorophenyl)imidazole. Based on results from our laboratory and others, it was becoming apparent that microsomal P450s exhibit remarkable conformational diversity and plasticity (Johnson and Stout, 2005; Poulos, 2005), which results in significant differences in the structure and placement of several secondary structural elements. These differences were apparent even in highly related P450s of the same subfamily, but the largest degree of structural plasticity had been observed in the CYP2B4 structures from our laboratory. These results suggest that microsomal P450s adopt an “induced fit” mechanism for ligand binding, where plastic regions are able to reorganize to accommodate the wide variety of P450 substrates without perturbing the overall P450 fold (Fig. 1). However, it was unknown what changes to the structure and active site of CYP2B4 would occur upon binding a molecule similar to one already observed in a crystal structure.

During the search for new crystallization candidates, 1-(4-chlorophenyl)imidazole (1-CPI) (Fig. 1A) displayed significant differences in binding affinity and thermodynamics, compared with its isomer 4-CPI. To determine the structural basis for these differences, the crystal structure of a CYP2B4-1-CPI complex was determined (Table 1) (Zhao et al., 2007). Overall, the tertiary structure of the complex was very similar to that of 4-CPI-bound CYP2B4 (Fig. 1C). However, repositioning of the side chains of Phe206, Phe297, and Glu301 led to a significantly different active site landscape. Phe206 and Phe297 exchanged positions, with Phe206 becoming a ligand-contact residue (Fig. 2A), while Glu301, rather than hydrogen bonding to the ligand, flips away from the active site (Fig. 2B) and interacts with His172. This causes an increase in active site volume from 200 Å³ in the 4-CPI complex to 280 Å³ in the 1-CPI complex. These findings highlight the ability of CYP2B4 to change the shape of its active site through the movement of a relatively small number of amino acid side chains.

1-Biphenyl-4-methyl-1H-imidazole. After observing the marked differences in tertiary structure in the CYP2B4 complexes of 1-CPI

![Fig. 2. Movement of active site residues in CYP2B-ligand complexes.](image-url)

To accommodate their various substrates and inhibitors, the closed forms of CYP2B enzymes show a reorientation of Phe206, Phe297, and Glu301. A, an overlay of the 1-CPI (yellow) and 4-CPI (blue) CYP2B4 complexes highlights the movement of Phe206 and Phe297. In the CYP2B4 complexes of 1-CPI and clopidogrel, the closed tBPA-modified CYP2B4 structure, and the CYP2B6 complexes of NBP and BP, Phe206 enters the active site, while Phe297 rotates out. In the 4-CPI complexes of CYP2B6 and CYP2B4, and the closed ligand-free CYP2B4 complexes, these two residues swap positions so that Phe206 is out and Phe297 swings in. B, an overlay of the CYP2B4 complexes of 4-CPI (blue), ticlopidine (green), and clopidogrel (teal) shows how Glu301 enters the active site to hydrogen-bond with 4-CPI and moves out of the active site to varying degrees in other CYP2B structures.
and 4-CPI compared with the bifonazole complex, it was unclear how the enzyme made the transition for such large structural reorganiza-
tions. To probe this mechanism, CYP2B4 was crystallized in the presence of another imidazole-based inhibitor of intermediate size
(Table 1). With two phenyl rings, 1-biphenyl-4-methyl-1H-imidazole
(1-PBI) (Fig. 1A) is larger than 1-CPI and 4-CPI but smaller than
bifonazole, which is branched and contains three phenyl rings. Like
CYP2B4-bifonazole, this structure also forms a crystallographic dimer, where the F’ helix of one monomer is buried in the active site
of its partner. As previously observed, the protein core of CYP2B4-
1-PBI does not change compared with other structures, whereas
movement of plastic regions allows the active site to accommodate the
inhibitor (Fig. 1E) (Gay et al., 2009). In this case, the B/C loop is
shifted away from the active site and contains two small helices. This
conformation is different from those observed in the CPI and bifen-
zole complexes of CYP2B4 as well as the ligand-free open structure.
The active site lid is formed by the F-G cassette and adopts a
conformation intermediate to those seen in the CPI and bifonazo-
le complexes. With its biphenyl rings pointing toward a conformation intermediate to those seen in the CPI and bifonazole,
while it is more compact in the BP, the B/C loop is shifted away
from the active site, which contains two small helices. This
conformation is different from those observed in the CPI and bifen-
zole complexes of CYP2B4 as well as the ligand-free open structure.
The active site lid is formed by the F-G cassette and adopts a
conformation intermediate to those seen in the CPI and bifonazo-
le structures. With its biphenyl rings pointing toward β-sheet 1, the ligand interacts with six residues (Ala298, Thr302, Ile363, Val367, Pro368, and Val477) in addition to coordinating to the heme iron. This represents a hybrid of the residues involved in bifenazole binding and those involved in 4-CPI binding, with three being common in each structure of CYP2B4-ligand complexes (Ala298, Thr302, and Ile363).

Analysis of the overall CYP2B4-1-PBI complex and comparison
with the other imidazole-bound structures of CY2B4 indicated that
a cluster of 10 phenylalanine residues at the intersection of the F, G, and H helices could be the key to allowing the F-G cassette to adopt new
conformations during ligand binding. These are Phe184, Phe188,
Phe195, Phe202, Phe203, Phe206, Phe244, Phe264, Phe296, and
Phe297. A sequence alignment of seven other family 2 P450s (data
not shown) showed that 8 of these 10 residues are either completely
or partially conserved. Before determining the 1-PBI structure, it was
not entirely clear how CYP2B4 accomplished the dramatic transition
from the tightly packed 1-CPI and 4-CPI structures to the wide-open
bifenazole conformation. Monitoring the position of these residues in
the CYP2B4 inhibitor complexes reveals significant variation as the
F-G cassette pivots across the I helix, which allows the enzyme to
adopt a predominantly open conformation in solution (Wilderman et
al., 2004; Gay et al., 2009) and ligand-free structures (Scott et
al., 2006). Furthermore, upon ligand binding, amide protons of plastic
regions are provided varying degrees of solvent protection depending
on the identity of that ligand. Peptides covering large portions of PR2
and PR4 showed significant slowing of the H-D exchange rate in the
presence of 4-CPI compared with ligand-free CYP2B4, consistent
with closed and open structures, respectively. In contrast, CYP2B4
with and without 1-PBI shows little difference in the H-D exchange
rate across the entire protein. This finding indicates that binding of
1-PBI does not increase protection from amide proton exchange for
the plastic regions of the protein in the B/C loop and the F-G cassette,
but it does not contradict the differences in conformation between the
crystal structures of open ligand-free and 1-PBI-bound CYP2B4. In
addition, because DXMS reports the average conformation in solu-
tion, these results also suggest that small populations of ligand-free
CYP2B4 could adopt the compact conformation observed in the
closed crystal structure (Wilderman et al., 2010).

**Molecular Dynamics.** To explore the energetically accessible con-
f ormations of CYP2B4 in the absence of ligand, a molecular dynamics
(MD) simulation was performed. The results showed that over time,
the closed ligand-free structure shifts to adopt a structure very differ-
ent from the starting model. A comparison of the final MD model to
the closed structure indicated that they differed by an RMSD value
similar to comparisons of the closed and 1-PBI-bound structures.
These changes in protein structure correlated to movements of the F-G
cassette and B/C loop during the simulation (Wilderman et al., 2010).
In solution, flexibility of these regions would allow CYP2B4 to bind
large compounds, such as 1-PBI and bifenazole, while also easily
accommodating smaller compounds such as 4-CPI.
CYP2B6. Despite accounting for only 2 to 10% of hepatic P450 content, CYP2B6 takes part in the metabolism of 3 to 12% of all drugs (Wang and Tompkins, 2008), including artemisinin, diazepam, nicotine, and bupropion (Zanger et al., 2007). With 28 known alleles, this highly polymorphic enzyme varies in expression levels and drug metabolism across populations (Zanger et al., 2007). These differences can lead to serious consequences during treatment with drugs such as efavirenz, which has a narrow therapeutic index and is primarily cleared by CYP2B6 (Ward et al., 2003). CYP2B6 activation of the prodrug cyclophosphamide may also be compromised because of altered enzyme activity (Xie et al., 2003; de Jonge et al., 2005). Based on these reports and others, we set out to crystallize a genetic variant of CYP2B6 bound to 4-CPI, which yielded the highest resolution ligand complex of CYP2B4. The crystallized protein (Table 1) contains the naturally occurring K262R mutation as well as an engineered Y226H mutation, which improves thermal stability.

The closed, compact structure of the CYP2B6-4-CPI complex (Fig. 1C) is very similar to that of CYP2B4 (Gay et al., 2010c). An overlay of the two structures yields an RMSD of 0.65 Å, which is lower than an overlay of the 1-CPI and 4-CPI complexes of CYP2B4 (0.76 Å). This indicates that ligand identity may have a greater impact on CYP2B protein conformations than does the primary sequence. The structural similarities between CYP2B4-4-CPI and CYP2B6-4-CPI are also evident in the active site (Fig. 3A), where the only difference in side chain identity is residue 363, which is Leu in CYP2B6 and Ile in CYP2B4. With regard to 4-CPI binding, the identity of residue 363 does not affect ligand orientation. However, studies have shown that mutating this residue in CYP2B6 affects oxidation of 7-butoxy coumarin, p-nitrophenol, and 7-ethoxy-4-trifluorocoumarin (Domanski et al., 1999; Spatzenegger et al., 2003), indicating that variability at this location could be key to explaining species differences in metabolism and product profiles among CYP2B enzymes. Despite their similarities, the 4-CPI complexes of CYP2B6 and CYP2B4 differ significantly in their active site cavity volumes, which are 582 Å3 and 253 Å3, respectively (Gay et al., 2010a). Rotation of Glu301 out of the CYP2B6 active site compared with CYP2B4 allows for the active site cavity to extend upward toward the F helix (Fig. 3B). On the opposite side of the active site, small rotations of Ile101 and Val477 facilitate the inclusion of another small pocket near the A helix and β-sheet 1. In light of the observed global plasticity of CYP2B4, it is interesting to note that the size and shape of CYP2B active sites can also change dramatically due to movement of a small number of side chains. It is also noteworthy that additional, unpreserved crystal structures of CYP2B6 (Table 1) in complex with 4-benzylpyridine (BP) and 4-(4-nitrobenzyl)pyridine (NBP) (Fig. 1A) also show rearrangement of active site residues Phe206 and Phe297 to accommodate the new ligands (Fig. 2A), rather than using larger, global movements of secondary structural elements as observed in some CYP2B4 complexes. These changes are similar to those observed in the 1-CPI and 4-CPI complexes of CYP2B4.

The K262R natural variant of CYP2B6 (allele CYP2B6*4) results from a single nucleotide polymorphism. In the X-ray crystal structure, the substituted Arg262 enters into a hydrogen-bonding network with nearby residues His252, Thr255, Asp263, and Asp266. These residues all occur on helices G and H, part of PR4, which has been observed in multiple positions in CYP2B4 structures. However, despite the movement of this region, this network of hydrogen bonds remains intact. An alignment of 10 CYP2B enzymes (data not shown) indicates that Lys262 in CYP2B6 is the only residue that is not conserved among these hydrogen-bonding partners. Alleles that contain a Lys at position 262, as in wild-type CYP2B6, could have altered positioning of the G helix as it moves above the I helix. These effects could be passed on to active site residues, changing the enzyme’s binding pocket. This may explain how polymorphic mutations in P450s occurring far from the active site affect ligand binding and catalysis.

CYP2B4 and Mobile Ligands. The degree of structural flexibility observed in the series of imidazole-bound structures of CYP2B4 is the largest reported among mammalian P450s. The movement of five plastic regions has shown that CYP2B4 is able to reorganize several secondary structural elements in response to ligand binding. However, it was unknown how these structures related to conformations of enzyme complexes of pharmaceutically relevant drugs. To explore the behavior of CYP2B4 drug complexes, we chose two compounds, clopidogrel and ticlopidine (Fig. 1A), which were expected to have greater freedom of movement in the binding pocket. Both are potent thienopyridine antiplatelet prodrugs, which are also strong MBIs of human CYP2B6 (Richter et al., 2004). Both drugs require activation by receptor P2Y12 by an irreversible modification of a cysteine residue.

X-Ray Crystallography of Ticlopidine and Clopidogrel Complexes of CYP2B4. Electron density maps for a CYP2B4-ticlopidine complex were equally valid for fitting the drug in two distinct orientations (Gay et al., 2010b), both of which are consistent with metabolic data gathered with other mammalian P450 enzymes (Tuong et al., 1981; Picard-Fraire, 1984; Ha-Duong et al., 2001; Dalvie and O’Connell, 2004; Ruan and Zhu, 2010). One orientation places the chlorophenyl moiety closer to the heme, while the other places the opposite end of the molecule bearing a thiophene ring closest to the heme. Because of its stereocenter, clopidogrel was easier to fit in the electron density and exhibited a single orientation, which points the chlorophenyl ring toward the heme. The Cα traces of both complexes aligned very well with each other and revealed a compact, closed structure (Fig. 1C) that resembles the conformation observed in the two previously determined CYP2B4 structures with the 4-CPI and
polypeptides, proteins, and enzymes. However, alternative uses of protein NMR has been used to determine the structure of entire molecules, while also being energetically favorable. The orientation in the active site gives CYP2B4 the flexibility to bind to the molecules. Adjusting both protein conformation and ligand orientation in the active site can be produced. This proved to be an excellent technique to investigate the preferred orientation of ticlopidine in the CYP2B4 active site (Gay et al., 2010b), where crystallographic studies yielded an ambiguous result. The results of these NMR experiments showed that $T_1$ paramagnetic relaxation rates for protons on the chlorophenyl ring were 71% higher than those of the thiophene group, indicating that the drug favors an orientation that places the chlorophenyl moiety closer to the heme than the thiophene group. Compared with the tight-binding imidazole inhibitors used in previous crystallographic studies, which are anchored to the heme, ticlopidine is in “fast exchange” in solution and likely adopts multiple conformations within the enzyme active site.

Metabolism of Ticlopidine by Human CYP2B6 and Rabbit CYP2B4. Although complementary NMR $T_1$ relaxation and MD simulations indicated that placing the chlorophenyl group of ticlopidine closer to the heme was the preferred orientation in CYP2B4, several metabolic studies of other P450s, including CYP2B6, have suggested that oxidation would occur preferentially from the other substrate orientations (Ha-Duong et al., 2001; Dalvie and O’Connell, 2004; Richter et al., 2004; Hagihara et al., 2008). Therefore, the oxidation of ticlopidine by reconstituted CYP2B4 was studied and compared with CYP2B6, in which the thiophene portion of the molecule was expected to orient toward the heme. In vitro incubation of both enzymes with ticlopidine resulted in the same set of metabolites: 7-hydroxyticlopidine (M1), 2-oxoticlopidine (M2), 5-(2-chlorobenzyl)thieno[3,2-c]pyridin-5-ium metabolite (M3), 5-(2-chlorobenzyl)thieno[3,2-c]pyridin-5-ium metabolite (M4), ticlopidine N-oxide (M5), and ticlopidine S-oxide dimer (TSOD), a dimerization product of ticlopidine S-oxide (M6) (Fig. 4) (Talakad et al., 2011). The rates of metabolite formation deviated significantly from linearity over time, which is consistent with the known inactivation of CYP2B6 by ticlopidine. Fitting data to a first-order equation resulted in similar rate constants ($k_{on}$) for both enzymes. However, the amount of M1 and M6 formation was four to five times greater in CYP2B6 than CYP2B4, indicating a longer residence time of ticlopidine with its thiophene ring closer to heme in CYP2B6. In contrast, CYP2B4 generated larger amounts of M4 and M5 than CYP2B6, indicating an alternate orientation with the nitrogen pointed toward the heme. These results indicate that the orientation of ticlopidine in the active site of CYP2B4 predicted by X-ray crystallography and NMR, which places the chlorophenyl moiety closest to the heme, is unproductive and that the drug possibly reorients within CYP2B4 to a more metabolically productive mode.

**CYP2B4 and Mechanism-Based Inactivators.** Mechanism-based inactivation by several classes of compounds has been used to probe the active site topology or catalytic mechanism of numerous P450s (Hollenberg et al., 2008). In CYP2Bs, acetylenic-based compounds have been the most widely studied (Roberts et al., 1993, 1994, 1998; Kent et al., 2002). In particular, tert-butyl acetylenes have proven especially useful as potent CYP2B inactivators, where they form adducts with the heme or active site residue Thr302 (Blobaum et al., 2005; Lin et al., 2009, 2010; Zhang et al., 2009). Despite complete modification of the threonine residue, partial enzymatic activity toward testosterone, 7-ethoxy-4-trifluorocoumarin, and benzphetamine was observed in the tBPA adduct of CYP2B4 (Zhang et al., 2009). To investigate the structural basis for these results, we used X-ray crystallography, DXMS, and molecular ligand docking to examine CYP2B4-tBPA (Gay et al., 2011) (Fig. 1A).

Two crystal structures of CYP2B4-tBPA (Table 1) were determined, where each shows a distinct protein conformation. In one form, the protein-tBPA adduct adopts a closed conformation similar to the CPI, ticlopidine, and clopidogrel complexes of CYP2B4 (Fig. 1C).
In the other structure, large movements of the B/C loop and F-G 1120 HALPERT

in solution that are dependent on the presence or

In accurate prediction of the metabolism of drug candidates is one of the long-term goals in the studies of P450s. This is challenging due to the conformational diversity and plasticity of drug-metabolizing P450s. X-ray crystal structures of CYP2B4 and CYP2B6 complemented by solution biophysical methods such as NMR, DXTS, and ITC have shown that CYP2B enzymes are able to accommodate their wide range of substrates and ligands in two ways, global and local plasticity. Similar to other family 2 enzymes, several ligand-bound structures of CYP2B2 have revealed a dynamic, closed active site that is able to reposition amino acid side chains, most notably Phe206, Phe297, and Glu301, to bind a large variety of chemically diverse compounds. However, more striking structural rearrangements of CYP2B4 have been observed in the presence of large imidazoles. These complexes result in markedly different conformations, which rely on the reorganization of highly mobile plastic regions, mainly the B/C loop and F-G cassette region. The large structural differences that have been captured in CYP2B4 crystals are also corroborated by DXTS results that show the enzyme is able to adopt several distinct conformations in solution that are dependent on the presence or absence of ligand and the identity of the ligand. Furthermore, ITC and NMR applications have given insight into the variability in binding of CYP2B4 ligands. Overall, the combination of these techniques has revealed a highly dynamic, highly adaptable subfamily of P450s. Applying these results to studies of P450-ligand interactions should aid in the design of safer, more efficient drugs.

Conclusions

Acknowledgments

I especially thank Dr. Sean C. Gay for expert help in preparing this manuscript and all the figures. The studies described represent the work of many talented postdoctoral fellows, visiting scientists, graduate students, and research assistants including Celia Balfour, Paul Ciaccio, Tammy Domanski, Dave Duignan, Sean Gay, Scott Grimm, You-ai He, You Qun He, Karen Kedzie, Santosh Kumar, Keiko Maekawa, B. K. Murakdilara, Art Roberts, Emily Scott, Manish Shah, Margit Spotzenegger, Jeff Stevens, Ling Sun, Grazyna Szklarz, Jyothi Talakad, Qinni Wang, Ross Wildermon, and Yong-hong Zhao. I also thank my many collaborators including Werner Braun, Chris Chin, Deepak Dalvie, Paul Hollenberg, Eric Johnson, Lauren Kaminz, Edward Morgan, Surendra Negi, Mike Wester, Mark White, Virgil Woods, and Qinghai Zhang. Special thanks go to Dave Stot who has been the senior crystallographer on all of our structures and who has done a fantastic job of teaching and mentoring a number of postdoctoral fellows.

Authorship Contributions

Participated in research design: Halpert.

Conducted experiments: Halpert.

Contributed new reagents or analytic tools: Halpert.

Performed data analysis: Halpert.

Wrote or contributed to the writing of the manuscript: Halpert.

James Halpert earned a B.A. in Scandinavian Languages from the University of California at Los Angeles in 1971, a PhD in Biochemistry from Uppsala University, Sweden in 1977, and a M.S. in Toxicology from the Karolinska Institute, Stockholm, Sweden in 1978. After 15 years on the faculty at the University of Arizona, he assumed the position of Professor and Chair of the Department of Pharmacology and Toxicology at the University of Texas Medical Branch in 1998. There he also served from 2003 to 2008 as Director of the National Institute on Environmental Health Sciences Center and Interim Director of the Sea Center for Environmental Health and Medicine. He also held the Mary Gibbs Jones Distinguished Chair in Environmental Toxicology. In March 2008, Dr. Halpert joined University of California, San Diego’s Skaggs School of Pharmacy and Pharmaceutical Sciences as Professor and Associate Dean for Scientific Affairs. He was a member of the National Institutes of Health Pharmacology Study Section from 1992 to 1995 and served as Chair from 1993 to 1995. He was Editor for *Drug Metabolism and Disposition* from 2000 to 2005 and is currently President of the American Society for Pharmacology and Experimental Therapeutics. Dr. Halpert’s research for the past 32 years has focused on the structure and function of cytochromes P450, especially the 2B and 3A subfamilies. The work has used a wide variety of biochemical, biophysical, and structural approaches and has focused on the mechanistic and structural basis of P450 inhibition and allostery.
