ABSTRACT:

The purpose of this work was to assess the pharmacokinetics and safety of lisdexamfetamine dimesylate (LDX) delivered and released regionally in the gastrointestinal (GI) tract. In this open-label, randomized, crossover study, oral capsules and IntelSite delivery capsules containing LDX (50 mg) with radioactive marker were delivered to the proximal small bowel (PSB), distal SB (DSB), and ascending colon (AC) during separate periods. Gamma scintigraphy evaluated regional delivery and GI transit. LDX and d-amphetamine in blood were measured postdose (<72 h). Treatment-emergent adverse events (TEAEs) were assessed. Healthy males (n = 18; 18–48 years) were enrolled. Mean (S.D.) maximal plasma concentration (C max) was 37.6 (4.54), 40.5 (4.95), 38.7 (6.46), and 25.7 (9.07) ng/ml; area under the concentration-time curve to the last measurable time point was 719.1 (157.05), 771.2 (152.88), 752.4 (163.38), and 574.3 (220.65) ng · h · ml −1, respectively, for d-amphetamine after oral, PSB, DSB, and AC delivery of LDX. Median time to C max was 5, 4, 5, and 8 h, respectively. Most TEAEs were mild to moderate. No clinically meaningful changes were observed (laboratory, physical examination, or electrocardiogram). LDX oral administration or targeted delivery to small intestine had similar d-amphetamine systemic exposure, indicating good absorption, and had reduced absorption after colonic delivery. The safety profile was consistent with other LDX studies.

Introduction

Drug delivery to sites of action is affected by physiochemical and physiologic variables (Farré and Camí, 1991). Physiochemical factors can affect absorption (lipid solubility, molecular size, and pKa). Greater lipophilicity tends to increase transfer across membranes compared with highly polar compounds that are not absorbed as readily (Shargel et al., 2005). Pharmacokinetic studies of different administration routes provide data on feasible delivery methods for enhanced gastrointestinal (GI) absorption, as indicated by relative rate and extent of absorption from optimal immediate- and/or sustained-release formulations (Volkow and Swanson, 2003; Spencer et al., 2006a). Some factors that affect absorption and bioavailability are dosage form, administration route, first-pass effect, and prodrug design (Farré and Camí, 1991). Physiochemical and pharmacologic properties, including the degree of aqueous and lipid solubility, extent of ionization, pKa, affinity for a tissue component, and formulation size, are not sufficient to fully characterize the extent of absorption from different GI segments. Thus, supplemental novel methods have been developed (Shargel et al., 2005).

Traditionally, in vitro dissolution tests followed by conventional pharmacokinetic studies, coupled with intubation and fluoroscopy methods, have been performed (Staib et al., 1986; Shargel et al., 2005). Although designed to assess drug absorption, these methods are not useful in establishing drug-release mechanisms (Davis et al., 1992). The intubation method involves the use of long feeding tubes that are usually introduced through the nasal passages, travel down the esophagus, and then enter the selected GI tract regions, typically including the early small intestine, the distal small intestine, and then the stomach, and then enter the duodenum, the jejunum, and finally the ileum. This method does not allow for the evaluation of regional delivery and transit of the drug in the GI tract.

This work was supported by Shire Development Inc., which provided funding to Sci Clinical Communications & Information for support in writing and editing this manuscript. Although the sponsor was involved in the design, collection, analysis, interpretation, and fact checking of information, the content of this manuscript, the ultimate interpretation, and the decision to submit it for publication in Drug Metabolism and Disposition were made by the authors independently. This work was previously presented as follows: Ermer J, Haffey M, Doll W, Martin P, Sandefer E, Buckwalter M, Trespidi L, and Page R (2010) Pharmacokinetic profile & safety of lisdexamfetamine dimesylate after target gastrointestinal release or oral administration in healthy adults. U.S. Psychiatric and Mental Health Congress; 2010 Nov 18–21; Kissimmee, FL. Continuing Medical Education, LLC, Jersey City, NJ.

the colon. A drug is then delivered to these segments over the course of a multiple-treatment study. This technique is uncomfortable for the participants and requires prolonged residence in the clinical facility, necessitating multiple fluoroscopies. The intubation tubes have an impact on GI motility (Read et al., 1983). A less invasive and more pharmacologically relevant technique is the use of remote-controlled drug-release systems, which include the high-frequency capsule (Battelle-Institute V, Frankfurt am Main, Germany) (Staub et al., 1986; Harder et al., 1990), InteliSite capsule (Casper Associates, Raleigh, NC), and Enterion capsule (Phaeton Research, Nottingham, UK) (Prior et al., 2004). Gamma scintigraphy (a well established radionuclide imaging technique) provides information on regional drug absorption and is a useful tool to evaluate various drug-delivery methods (Davis et al., 1992; Meseguer et al., 1994). Non-biodegradable, non-invasive InteliSite Companion Capsules (ICCs) with radiolabeled content are spring-loaded and are designed to actively deliver drug in selected regional segments of the GI tract. The capsule is opened after a radiofrequency signal is sent from the amplifier, resulting in release and dispersion of the drug and the surrogate radioactive marker, which is visualized via gamma scintigraphy. When used with conventional pharmacokinetic assessment, scintigraphy and the remote-controlled capsules can be used to determine regional drug absorption and evaluate comparative relative bioavailability (Connor et al., 2001). Although this technology allows visualization of the radioactive component rather than the drug, the drug’s dispersion at the site of absorption can be monitored (Davis et al., 1992). The timing and extent of formulation dispersion, coupled with knowledge of GI transit values after drug release and of the drug’s solubility, can be correlated with classic pharmacokinetics to interpret the degree of drug absorption versus control.

Psychostimulants, amphetamines, and methylphenidate are first-choice treatments for attention-deficit/hyperactivity disorder (ADHD) symptom management (Pliszka et al., 2006). Lisdexamfetamine dimesylate (LDX) Vyvanse; Shire US Inc., Wayne, PA) is a long-acting prodrug stimulant indicated for the treatment of ADHD in children (6–12 years), adolescents (13–17 years), and in adults. After oral ingestion, LDX (therapeutically inactive molecule) is converted to l-lysine and active d-amphetamine (therapeutically active) (Fig. 1) (Pennick, 2010). The conversion of LDX to d-amphetamine is unlikely to be affected by GI pH and variations in normal GI transit times (Shojai et al., 2007; Krishnan and Zhang, 2008; Haffey et al., 2009). Although a small amount of LDX is hydrolyzed to d-amphetamine in the GI tract, the conversion of LDX into active d-amphetamine occurs primarily in the blood (Pennick, 2010). LDX absorption likely occurs via a high-capacity carrier-mediated transport system involving peptide cotransporter 1 (PEPT1) in the small intestine, although the involvement of other peptide and amino acid transporters cannot be ruled out (Pennick, 2010). More detailed knowledge of LDX absorption throughout the GI tract may provide useful information to substantiate and extend our understanding of the mechanisms responsible for its absorption. Hence, the study objective was to assess the pharmacokinetics of LDX when released into targeted GI tract regions compared with LDX pharmacokinetics with oral administration.

Materials and Methods

Study Overview. This trial was a single-center (Scintipharma Inc., Lexington, KY), open-label, two-phase, randomized crossover study designed to investigate the pharmacokinetics and safety of LDX in healthy adults. It was designed to compare the pharmacokinetic parameters of LDX administration, when delivered by a single oral dose, with those of regional delivery in the GI tract to the proximal small bowel (PSB), distal SB (DSB), and ascending colon (AC). Results from the intranasal (IN) delivery portion of this study have been separately reported (Ermer et al., 2011).

This study was conducted in accordance with the principles of the 18th World Medical Assembly (Helsinki, Finland, 1964) and amendments of the 29th (Tokyo, Japan, 1975), 35th (Venice, Italy, 1983), 41st (Hong Kong, 1989), and 48th (South Africa, 1996) World Medical Assemblies, Declaration of Helsinki, and Good Clinical Practice according to the International Conference on Harmonisation guidelines. The study protocol was approved by an independent institutional review board (Chesapeake Research Review, Inc., Columbia, MD). Before screening, written informed consent using an institutional review board-approved consent form was obtained.

Participants. Normal, healthy adult male participants between ages 18 and 65 years who agreed to use an acceptable method of contraception during the study and for 1 week after the last evaluation were eligible for inclusion in the study. To be included, participants also needed to test negative for HIV and the hepatitis B surface antigen and hepatitis C antibody screen. Participants also had to have a satisfactory medical assessment with no clinically significant and relevant abnormalities. Other criteria included a body mass index of 20 to 29 kg/m² inclusive and the ability to swallow capsules and comply with study procedures.

Study Design. Screening was performed between 28 and 3 days before receiving the first dose of study drug, and inclusion and exclusion criteria were reviewed again upon admission to determine eligibility. Participants were randomized to a treatment sequence and were required to fast overnight (≥8 h) before LDX administration. Non-biodegradable and noninvasive ICCs were designed to actively deliver drugs with spring-loaded action to various areas of the GI tract upon radiofrequency signal (Pithavala et al., 1998; Parr et al., 1999). The ICC has been used to determine regional drug absorption and bioavailability, with its radiolabeled content visualized via gamma scintigraphy. Indium-111 (111In) chloride (25 μCi) was the surrogate radioactive marker used to track the capsule throughout the GI tract to the targeted site of delivery, as well as to confirm and monitor the dispersion of the released drug formulation after capsule opening; technetium-99m-diethylenetriamine-pentaacetic acid (99mTc-DTPA; 50 μCi) was coadministered with the drink when the capsule was swallowed and was used for GI anatomy visual confirmation by scintigraphy.

The five dosing periods of the study were made up of two administrations, oral and IN regimens during phase 1, as previously reported (Ermer et al., 2011), and three administrations, PSB, DSB, and AC regimens during phase 2. The oral regimen consisted of a 50-mg LDX capsule that was not radiolabeled...
and was delivered orally with 240 ml of water. The IN delivery regimen was a single 100-μl preparation (50 mg of LDX in 0.9% saline) that also contained up to 100 μCi of ⁹⁹mTc-DTPA, which has been previously reported (Ermer et al., 2011) and is not presented here. Each ICC delivery regimen (PSB, DSB, and AC) was prepared as a single preparation (the equivalent of 50 mg of LDX was dissolved in water and filled into an ICC, containing up to 25 μCi of ¹¹¹In chloride). The ICCs were administered orally with 120 to 240 ml of water, followed by 240 ml of a radioabeled drink (¹⁹⁹mTc-DTPA, ~50 μCi). The 50 mg/day dose strength of LDX used in this study is equivalent to an amphetamine base dose of 14.8 mg/day (Findling et al., 2009).

The two-way crossover (two dosing periods conducted during phase 1 as a two-sequence treatment regimen: oral versus IN) has been previously reported (Ermer et al., 2011). The three-way crossover (three dosing periods) was performed in phase 2, and the treatment regimen included six sequences (Fig. 2). Participants received PSB, DSB, and AC regimens by ICC delivery, as indicated in the randomization schedule. The dosing day for each dosing period was separated from the next by at least 7 days. If necessary, a maximum of seven administrations could be received (two additional ICCs in phase 2).

Each participant was assigned to a specific treatment regimen sequence that could be adjusted in certain circumstances (e.g., GI transit). Confinement began 1 day before the dosing period, and participants remained in the unit and were not discharged until approximately 48 h after drug release from the ICC. After taking the ICC, the participant continued fasting for an additional 4 h (beyond the 8 h before dose administration) as long as the ICC had emptied from the stomach. If the ICC had not emptied from the stomach, the fast was continued until gastric emptying was confirmed. Water was permitted ad libitum until 2 h before the dose and after 2 h postdose. Participants were asked to return to the unit 72 h after ICC opening for pharmacokinetic blood sampling and 7 to 14 days after the completion of the final study phase or withdrawal for follow-up examination.

Pharmacokinetics. The primary study outcome was to determine the pharmacokinetic parameters of intact LDX and d-amphetamine from LDX after oral and GI delivery. The safety population consisted of enrolled participants who took one or more doses of LDX and had completed one or more follow-up safety assessments. The pharmacokinetic population was defined as all participants in the safety population who had evaluable concentration-time profiles for LDX or d-amphetamine from LDX. Blood samples (3 ml) were collected at 0 (predose or before release of ICC), 15, 30, and 45 min and at 1, 1.5, 2, 3, 4, 5, 6, 8, 12, 16, 24, 36, 48, and 72 h postdose for the oral regimen or after drug release from the ICC for the PSB, DSB, and AC regimens. Blood samples were collected in K₂EDTA tubes placed on ice and then centrifuged at approximately 4°C. The plasma from the sample for each participant was collected in two polypropylene tubes. One tube was shipped on dry ice to a laboratory for analysis, and the other was stored at −75°C as backup.

Plasma d-amphetamine from LDX and intact LDX concentrations were measured using a validated liquid chromatography with tandem mass spectrometry method. The method used liquid-liquid extraction, followed by analysis on a Sciex API 3000 (PerkinElmer Life and Analytical Sciences, Waltham, MA) tandem mass spectrometric detection in a heated nebulizer positive ionization mode equipped with liquid chromatography. The lower and upper limits of quantification, respectively, were 1.00 and 100.00 ng/ml for intact LDX and 2.00 and 200.00 ng/ml for amphetamine using a 200-μl plasma aliquot. Quality-control (QC) samples were prepared in control human plasma at three concentration levels and were assayed with each set of samples against freshly prepared calibration standards. The QC sample concentrations of LDX and amphetamine were 3, 20, and 80 ng/ml, and 6, 40, and 160 ng/ml, respectively. Concentrations below the lower limit of quantification were reported as nonquantifiable.

In this study, QC samples and calibration standards were found to be within acceptable limits based on the U.S. Food and Drug Administration Guidance for Industry; Bioanalytical Method Validation (http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm070107.pdf, 2010). For LDX, the mean concentrations were 2.91, 19.53, and 78.23 ng/ml for low-QC (3 ng/ml), mid-QC (20 ng/ml), and high-QC (80 ng/ml) standards, respectively. For d-amphetamine, the mean concentrations were 5.76, 39.50, and 150.83 ng/ml for low-QC (6 ng/ml), mid-QC (40 ng/ml), and high-QC (160 ng/ml) standards, respectively.

Gamma Scintigraphy. Gamma scintigraphy was used to monitor ICC integrity, drug release, and transit after drug release (Digenis and Sandefur, 1991; Davis et al., 1992) to examine the absorption of LDX released in the GI tract after ICC delivery regimens (PSB, DSB, and AC). The radioactive isotopes ⁹⁹mTc and ¹¹¹In were monitored simultaneously because of their different energies of gamma-ray emission and because they are not absorbed in the GI tract. To monitor GI transit of the ICC, the ¹¹¹In chloride was included with LDX in the capsule, and to delineate the target sites, the water used to swallow the ICC contained ⁹⁹mTc-DTPA. The remote-controlled ICC was opened with an external signal for release once it reached the appropriate anatomic region. Subsequently, blood samples were collected to assess absorption.

A series of images, 1 min each, were taken from participants in the supine position. For the PSB and DSB delivery regimens, the images were conducted at approximately 15- to 30-min intervals until ICC drug release and, at a minimum, to coincide with blood-sampling times. For the AC delivery regimen, the images were recorded at approximately 30-min intervals until gastric emptying had occurred and for the same amount of time until capsule drug release. Subsequently, images were collected at a minimum to coincide with blood-sampling times.

Safety. The maximal amount of radioactivity to be administered including the potential for up to two additional repeat administrations was 250 μCi of ⁹⁹mTc-DTPA (50 μCi per administration of ICC) and 125 μCi of ¹¹¹In chloride (25 μCi per administration of ICC). The maximal radiation dose for the study was 1.849 mSv and was within limits of the recommended permissible standard allowable radiation for individuals with infrequent annual exposure, which is 5 mSv (National Council on Radiation Protection and Mea-
Plasma pharmacokinetic parameters of intact LDX for the pharmacokinetic population by oral and ICC GI delivery are summarized in Table 1 and are illustrated in Fig. 3. For intact LDX, a comparison of pharmacokinetic parameters (AUC_{0-last}, AUC_{0-inf}, and C_{max}) for the ICC delivery regimens (PSB, DSB, and AC) to those of oral regimens is presented in Table 2. At 1 h postdose, the intact LDX plasma concentration profiles varied, with mean (S.D.) values ranging from 2.1 (3.40) to 30.0 (12.93) ng/ml across regimens. After 1.5 h, the LDX plasma concentrations for oral, PSB, and DSB were similar, whereas

![Graph](image-url)
the mean (S.D.) gastric emptying time was 2.7 (5.38) h. The participants
were then removed from the camera, and the signal was sent to the
ICC at a mean (S.D.) time of 3.3 (5.59) h postdose to open the capsule.
The mean (S.D.) time after opening of the ICC for 50% of the
radioactive marker released from the ICC to arrive at the colon
(postdose arrival time50%; ATC50%) was 9.6 (5.65) h. The mean (S.D.)
time for 50% of the marker to move through the small intestine
and arrive at the col on after release of the marker from the ICC
(small intestine transit time50%; SITT50%) was 6.4 (4.09) h. The mean (S.D.)
AUC of small intestine (proximal and distal) GI transit curve (AUCG1)
after the radioactive marker release was 6.4 (3.89) units (fraction of
radioactive marker in GI region of interest × hour). The mean (S.D.)
evacuation time postdose of the opened ICC in all participants in the
feces was 28.9 (11.22) h.

For DSB delivery, scintigraphic imaging indicated that the mean
(S.D.) gastric emptying time was 2.6 (4.47) h and the opening of
the capsule for AC delivery was at a mean (S.D.) of 10.1 (5.41) h after
the ICC was visualized in the cecum. The mean (S.D.) ATC for the
unopened ICC in the colon was 8.3 (5.56) h, and the mean (S.D.) SITT
calculated as the ATC minus gastric emptying was 5.7 (2.24) h. The
mean (S.D.) evacuation time postdose of the opened ICC in the feces
was 30.0 (20.41) h.

Safety. On day 1 of a dosing period, 18 participants received LDX
orally in phase 1; in phase 2, LDX was administered using an ICC in
17 participants to target the PSB, in 17 participants to target the DSB,
and in 16 participants to target the AC. Sixteen participants received
all five regimens and completed the study. There were no serious
TEAEs and no treatment-related withdrawals. One participant refused
to swallow the ICC capsule and was discontinued. The number of
participants reporting any TEAEs and the incidence of any TEAEs
reported were similar for all regimens: oral [5 of 18 participants

bowel delivery resulted in predictable and similar or small bowel delivery (i.e., PSB and DSB), but LDX was not as well resolved within 4.5 h. There were no serious TEAEs, participant withdrawals or discontinuations, or deaths. Moreover, no clinically meaningful changes in mean laboratory parameters, physical examination findings, or electrocardiogram occurred during the study.

Discussion

Absorption (systemic exposure) of LDX was comparable after oral or small bowel delivery (i.e., PSB and DSB), but LDX was not as well absorbed after AC delivery. LDX administration by oral or small bowel delivery resulted in predictable and similar d-amphetamine plasma concentration profiles and pharmacokinetics. LDX delivery to the AC produced less LDX and d-amphetamine exposure compared with the other regimens. These data suggest that LDX can be effectively and readily absorbed when delivered to various segments of the GI tract. Scintigraphy data in this study confirmed that targeted LDX delivery to the PSB, DSB, and AC with the ICC was achieved. Overall, these data also suggest that the absorption windows for LDX release in the small intestine were similar to those achieved with oral administration; drug delivery and absorption in the AC, though less, were effective.

In relation to LDX absorption in the AC, it is intriguing that low levels of LDX absorption, based on the nature of the slower movement and permeability in the colon, most likely due to the limited motility, decreased fluid content, and increased viscosity of this segment, coupled with the relatively rapid conversion of LDX upon absorption and minimal LDX accumulation. By this paradigm, LDX accumulation in the blood would be lower after colonic absorption, and the LDX being absorbed would be converted rapidly, resulting in the disproportionately higher plasma levels of d-amphetamine relative to those of LDX.

Results from this study and other LDX studies suggest that its solubility profile is not affected by pH within the biological range, whether delivered with an ICC or orally (Shojaei et al., 2007). Moreover, increasing the pH above this range resulted in only slight reductions in LDX solubility. Supportive of these data is an in vitro assay, in which LDX was not converted by enzymes that simulated conditions of the GI tract, inclusive of gastric and intestinal fluids; this is consistent with intact LDX absorption in the body (Pennick, 2010).

LDX is composed of the amino acid l-lysine covalently linked to d-amphetamine by a dipeptide-like linkage (Fig. 1) (Pennick, 2010). Although a small amount of LDX is hydrolyzed to d-amphetamine in the GI tract, the conversion of LDX into active d-amphetamine occurs primarily in the blood (Pennick, 2010). GI absorption of drugs may be affected by saturation of a carrier-mediated absorption pathway, drug instability with pH, metabolism (e.g., GI mucosa), protein binding, and other factors (Ratnai, 1992). As reviewed by Lin (2007), oral absorption is often affected by gastric emptying time and low intestinal motility. Long-term alterations in GI physiology such as aging, inflammatory bowel disease or other GI diseases, surgical removal of the GI tract, cystic fibrosis, and AIDS affect pH, transport, absorption area, and acid secretion (Fleisher et al., 1999). The ICC noninvasive delivery method to the small intestine and colon used in this study provided information on absorption in these regions under physiologic conditions. This method may prove useful in probing characteristics of targeted GI absorption to elucidate factors that affect regional absorption of drugs.

Various pharmacokinetic studies of psychostimulants have indicated consistency in terms of bioavailability with various formulations of mixed amphetamine salts extended release or methylphenidate (Ermer et al., 2007a; Tuerck et al., 2007), but the prodrug mechanism of LDX suggests more-consistent pharmacokinetics. A study in children with ADHD demonstrated that d-amphetamine from LDX is

Note: Time zero for PO regimen is time of dosing. Time zero for PSB, DSB, and AC regimens is time of ICC opening.
dose-proportional and exhibited low intersubject variability after single-dose administration (Boelner et al., 2010). Plasma concentrations of d-amphetamine measured over time increased linearly in a dose-dependent manner after oral doses of LDX, with no indication of enzyme saturation in healthy adults, and exhibited low intersubject and intrasubject variability (Ermer et al., 2010). These data indicate reliable delivery of the active drug over a wide dose range upon prodrug administration. These effects may likely be attributed to the prodrug mechanism of LDX, which requires intrinsic enzymatic cleavage of intact LDX to active d-amphetamine and is not dependent on typical exogenous formulations or drug-release delivery systems such as are characteristic of other stimulants (Ermer et al., 2007b).

Physical and chemical interactions may occur between drugs and food, other drugs, or formulation components (Fleisher et al., 1999). Physiochemical and biological characteristics of LDX (e.g., high water solubility, lack of effect on absorption or conversion by changes in gastric environment and pH, and gradual conversion to active d-amphetamine) may contribute to the consistent delivery of d-amphetamine and low variability among participants [Vyvanse (package insert), 2011]. There are several factors that may affect absorption in general that should be considered for LDX. For example, absorption rate of a drug may be increased with increases in dissolution rate. On the other hand, increases in the degradation rate of drugs may decrease luminal concentration and limit the extent of absorption (Fleisher et al., 1999). Another factor that may delay or decrease drug absorption is reduction in the rate of radial diffusion in the intestinal lumen (Fleisher et al., 1999). An example of an interaction that has been shown to have significant effects on absorption is food intake. It is primarily dependent on meal size and the physiochemical properties of the actual drug, which may reduce, delay, increase, accelerate, or have no effect on absorption (Fleisher et al., 1999; Lin, 2007). In particular, in the case of LDX, food had no effect on the systemic exposure of d-amphetamine; however, it delayed \( T_{\text{max}} \) of d-amphetamine and intact LDX by approximately 1 h in healthy participants with a high-fat meal (Shojaei et al., 2007; Krishnan and Zhang, 2008).

Therefore, LDX may be taken with or without food or may be dissolved in water without affecting absorption (Goodman, 2007). Because LDX is a prodrug (not a controlled-release vehicle), it is dissolved in water without affecting absorption (Goodman, 2007). with a high-fat meal (Shojaei et al., 2007; Krishnan and Zhang, 2008). amine and intact LDX by approximately 1 h in healthy participants

In conclusion, LDX was well absorbed (systemic exposure) after oral or small bowel delivery regimens and demonstrated identical d-amphetamine plasma concentration profiles and results. AC delivery produced less exposure to LDX and d-amphetamine compared with other regimens. Overall, LDX treatment regimens demonstrated a safety profile consistent with that demonstrated in other LDX clinical studies, with no unexpected safety findings or results of clinical concern.
