**ABSTRACT**

Cholestasis, a hallmark feature of hepatobiliary disease, is characterized by the retention of biliary constituents. Some of these constituents, such as bile acids, inflict damage to hepatocytes and bile duct cells. This damage may lead to inflammation, fibrosis, cirrhosis, and eventually carcinogenesis, sequelae that aggravate the underlying disease and deteriorate clinical outcome. Canalicular ATP-binding cassette (ABC) transporters, which mediate the excretion of individual bile constituents, play a key role in bile formation and cholestasis. The study of these transporters and their regulatory nuclear receptors has revolutionized our understanding of cholestatic disease. This knowledge has served as a template to develop novel treatment strategies, some of which are currently already undergoing phase III clinical trials. In this review we aim to provide an overview of the structure, function, and regulation of canalicular ABC transporters. In addition, we will focus on the role of these transporters in the pathogenesis and treatment of cholestatic bile duct and liver diseases.

**Introduction**

Hepatic ATP-binding cassette (ABC) transporters play a key role in cholestatic disease and are expressed at the basolateral and apical membrane of liver cells (hepatocytes). Canalicular ABC transporters are responsible for the formation of bile and secrete bile acids (ABC11) (Gerloff et al., 1998), bilirubin (ABC2) (Paulusma et al., 1997), phosphatidylcholine (ABC4) (Smith et al., 1993), cholesterol (ABCG5/G8) (Berge et al., 2000), and drugs (ABC1B, ABC2B, ABC2C) across the bile canalicular membrane. ABC1111 transports bile acids against a steep (1000-fold) concentration gradient. This gradient attracts water into the bile canalicular lumen and thereby drives bile flow. Mixed micelles of phosphatidylcholine (ABC4) and cholesterol (ABCG5/G8) incorporate these bile acids and thereby mitigate their detergent effects (reviewed by Trauner et al., 2008).

This work was supported by funding from the Austrian Science Fund (FWF) project “Transmembrane Transporters in Health and Disease” [Grant SFBF35]. Please note that abbreviations for transporters and nuclear receptors were capitalized throughout this article when symbols were identical for human and rodents.

dx.doi.org/10.1124/dmd.113.056358.

**ABBREVIATIONS:** ABC, ATP-binding cassette; ABCB1, ATP-binding cassette, subfamily B, member 1; ABCB11, ATP-binding cassette, subfamily B, member 11; ABCB4, ATP-binding cassette, subfamily B, member 4; ABCCC2, ATP-binding cassette, subfamily C, member 2; ABCG2, ATP-binding cassette, subfamily G, member 2; ABCG5/G8, ATP-binding cassette, subfamily G, members 5/8; CAR, constitutive androstane receptor; CITCO, 6-(4-chlorophenyl)-imidazo[2,1-b][1,3]thiazole-5-carbaldehyde; FXR, farnesoid X receptor; GR, glucocorticoid receptor; ICP, intrahepatic cholestasis of pregnancy; IL, interleukin; LPAC, low phospholipid associated cholestasis syndrome; LXR, liver X receptor; MDR1, multidrug resistance protein 1; P-glycoprotein; MDR2 (rodent)/MDR3 (human), multidrug resistance protein 2 (rodents)/3 (human); norUDCA, norursodeoxycholic acid; NR, nuclear receptor; NTCP, sodium taurocholate cotransporting polypeptide; NR, nuclear receptor; PBC, primary biliary cirrhosis; PC, phosphatidylcholine; PFLC, progressive familial intrahepatic cholestasis; PPARα, peroxisome proliferator-activated receptor alpha; PPARδ, peroxisome proliferator-activated receptor gamma; PSC, primary sclerosing cholangitis; PXR, pregnane X receptor; RXRα, retinoic acid receptor alpha; RXRβ, retinoid X receptor alpha; SPP, short heterodimer partner; SNP, single-nucleotide polymorphism; SULT2A1, sulfotransferase 2A1; TPN, total parenteral nutrition; UDCA, ursodeoxycholic acid; UGT1A1, UDP glucuronosyltransferase 1A1; UGT2B4, UDP glucuronosyltransferase 2B4; VDR, vitamin D receptor.
formation and cholestasis. To provide a basis for this undertaking, we will commence with a brief overview of bile acid metabolism. Subsequently, we will turn our attention to the individual canalicular transporters and review their structure, function, associated substrates, and regulation in health and disease. In the last part of the review, we will focus on the potential role of these transporters and the NRs that regulate their transcription as drug targets in cholestatic disease. Many of the studies described in this review were performed in mice, which have a significantly different bile acid pool compared with humans. The direct extrapolation of animal data to human physiology is therefore not possible without their verification in human models. Although the animal studies discussed in this review were invaluable for our understanding of bile metabolism, their interpretation thus needs careful appreciation of interspecies discrepancies.

Bile Acid Metabolism and Its Regulation

Bile acids are synthesized from cholesterol in the liver. This synthesis requires 17 enzymatic steps, of which the conversion of cholesterol into 7α-hydroxycholesterol by 7α-hydroxylase is considered to be rate-limiting. Most (>99%) bile acids are directly conjugated (either with taurine or with glycine), which necessitates their active secretion (via ABCB11 and ABC2) across the bile canalicular membrane. The secreted bile acids then enter the intestinal lumen and are efficiently (>95%) reabsorbed, mostly by the apical sodium-dependent bile acid transporter in the terminal ileum (Dawson et al., 2003). The reabsorbed bile acids return to the liver via the portal circulation, from where they are extracted by the basolateral uptake transporters of the hepatocyte. The sodium/taurocholate cotransporting polypeptide (NTCP) transports the majority (~90%) of these bile acids, whereas multispecific organic anion transporters play a comparably modest role in hepatocellular bile acid uptake (Hagenbuch and Meier, 1994; Kullak-Ublick et al., 1994).

NRs regulate the transcription of hepatic genes that are involved in bile acid homeostasis (Fig. 1; reviewed by Halilbasic et al., 2013). These receptors act as intracellular sensors and prevent the accumulation of toxic bile acid compounds. Activated NRs change conformation, recruit coactivators (and/or dissociate from corepressors), and induce/repress transcription either by binding the DNA of their target genes or by interacting with other NRs. The role and function of NRs is exemplified by the farnesoid X receptor (FXR), which acts as an intracellular sensor for bile acids (Fig. 2) (Makishima et al., 1999; Parks et al., 1999; Wang et al., 1999). Bile acid-activated FXR forms a heterodimer with the retinoid X receptor (RXR), which then binds an inverted repeat-1 sequence (or other response elements) in the promoter of its target genes (Forman et al., 1995; Seol et al., 1995; Laffitte et al., 2000). The resulting gene transcription decreases hepatocellular bile acid uptake (NTCP) and synthesis (CYP7A1/CYP8B1), while promoting canalicular (ABCB11, ABC2) and basolateral bile acid excretion in rodent and human hepatocytes (Ananthanarayanan et al., 2001; Denson et al., 2001; Gerloff et al., 2002; Kast et al., 2002; Plass et al., 2002; Eloranta and Kullak-Ublick, 2005). These effects are partly mediated by the FXR-induced activation of the short heterodimer partner (SHP), which represses the transcription of NTCP, CYP7A1, and CYP8B1 (Fig. 1) (Brendel et al., 2002; Gupta et al., 2002; Abrahamsson et al., 2005; Kir et al., 2012). FXR also induces bile acid detoxification via CYP3A4, SULT2A1, and UGT2B4, which further protects the hepatocyte from bile acid–induced damage (reviewed by Zollner et al., 2006). Finally, FGFR9, which is expressed in the human liver and intestine, can also be induced by FXR (Holt et al., 2003; Inagaki et al., 2005; Kim et al., 2007; Schaap et al., 2009). This last mechanism represents a negative feedback loop, which can be induced by an increased intestinal or hepatic bile acid concentration (e.g., after a meal) (Choi et al., 2006). Other NRs such as the pregnane X receptor (PXR) and the constitutive androstane receptor (CAR) are also involved in bile acid metabolism. Both receptors are best known for their role in phase I (cytochromes P450), phase II (conjugation), and phase III (transport proteins) drug elimination. PXR and CAR are, however, also activated by hydrophobic bile acids (PXR) and bilirubin (indirect activation; CAR) in rodent and human hepatocytes (Staudinger et al., 2001; Xie et al., 2001; Huang et al., 2003b). This activation induces hepatocellular bile acid excretion (ABCC2, ABCC3, ABCC4) and detoxification (CYP3A4/CYP2B10/SULT2A1) (Xie et al., 2000; Marschall et al., 2005; Chai et al., 2011, 2012) and stimulates bilirubin conjugation (UGT1A1 and excretion (ABCC2) (Huang et al., 2003b; Marschall et al., 2005). PXR also represses bile acid synthesis (via CYP7A1) (Staudinger et al., 2001). The vitamin D receptor (VDR) is activated by secondary bile acids such as lithocholic acid (Makishima et al., 2002). The impact of VDR activation on bile acid metabolism and cholestatic disease is difficult to predict, because it inhibited FXR-dependent gene transactivation in vitro, but also had antiinflammatory effects in a rat model of liver fibrosis (Honjo et al., 2006; Abramovitch et al., 2011). VDR does not seem to have a significant impact on the expression of canalicular ABC transporters. Several non bile acid activators, such as peroxisome proliferator-activated receptors (PPARs) and the glucocorticoid receptor (GR), are also involved in bile acid detoxification and elimination (Fig. 1), but an extensive discussion on their role in bile acid metabolism falls beyond the scope of this review.

ABCB11

ABCB11 acts as the canalicular bile salt export pump and transports conjugated monovalent bile acids from the hepatocyte into the bile. This transport not only protects the liver from bile acid–induced toxicity, but also represents the major driving force for (bile acid-dependent) bile flow. As the major canalicular bile acid transporter in humans, ABCB11 plays a key part in bile formation and (hereditary) cholestasis.

ABCB11 is a 160-kDa member of the B subfamily (ABCB) of ABC transporters and has a structure that consists of two nucleotide-binding and two 6-helical transmembrane domains (Fig. 3) (Kubiz et al., 2012). ABCB11, like ABC2, ABCB4, ABCB1, and ABCG5/8, is an exclusively apical transporter. Its expression pattern is restricted to hepatocytes, which supports its role in canalicular bile acid transport and bile formation. Human ABCB11 transports conjugated/amidated monovalent bile acids (Table 1) in the following order of clearance: taurochenoxycholic acid > glycochenoxycholic acid > taurocholic acid > glycocholic acid (Hayashi et al., 2005). ABCB11 thus clears chenoxycholic acid, which is the most toxic of these bile acids, with the greatest efficacy (Hayashi et al., 2005; Song et al., 2011). Interestingly, some in vitro reports suggested that ABCB11 might also transport drugs (e.g., vinblastine, taxol, and pravastatin) (Childs et al., 1998; Llecureur et al., 2000; Hirano et al., 2005). The impact of ABCB11 on drug transport, however, has not been established.

A decrease in ABCB11 activity leads to bile acid accumulation and plays an important role in the pathogenesis of acquired and hereditary cholestatic disease. Prescription drugs, inflammation, and total parental nutrition (TPN), for example, can all lead to acquired cholestasis. Drugs, such as cyclosporine A, glybenclamide, rifampicin, and rifamycin, can repress ABCB11 activity via competitive inhibition. The resulting decrease in canalicular bile acid transport can lead to drug-induced cholestasis, which will generally resolve quickly after drug withdrawal (Stieger et al., 2000). Inflammation and TPN repress canalicular ABCB11 expression in rodents (Nishimura et al., 2005; Recknagel et al., 2012).
This decrease, which occurs via various (post-) transcriptional mechanisms, can contribute to the development of inflammatory/septic or TPN-induced cholestasis. ABCB11 polymorphisms can predispose to acquired cholestatic disease, and the single-nucleotide polymorphism (SNP) rs2287622 has a relatively high prevalence in patients with drug-induced cholestasis, intrahepatic cholestasis of pregnancy, liver fibrosis, and cholangiocarcinoma (reviewed by Steiger and Beuers, 2011). Severe ABCB11 mutations can lead to the development of hereditary cholestasis, which covers a mild to severe phenotypical spectrum. Progressive familial intrahepatic cholestasis type 2 (PFIC2) leads to severe cholestasis and is generally associated with a nonfunctional ABCB11 protein (reviewed by Jacquemin, 2012). This disease usually manifests itself...
ABC Transporters and Cholestasis

Fig. 3. The principal structure of canalicular ABC transporters. The structure of canalicular ABC transporters can consist of 1, 2, or 3 transmembrane domains (for details kindly refer to the text). The ABCB (B1, B11) and ABCG (G2, G5, G8) transporter family members mentioned in the text have comparable structures and are therefore not shown separately in this figure.

within the first 6 months of life. Patients typically suffer from cholestasis, fat malabsorption, growth retardation, and an increased risk for hepatocellular carcinoma (Knisely et al., 2006). The initial treatment usually consists of ursodeoxycholic acid (UDCA), fat-soluble vitamins (D, K), cholestyramine (for pruritus), and biliary diversion (Emond and Whitington, 1995). Most patients, however, will require liver transplantation in the first 2 decades of life. Some transplanted patients develop rebound cholestasis due to formation of anti-ABCB11 antibodies (Keitel et al., 2009). Treatment options for PFIC2 patients with a nonfunctional protein remain limited in the absence of gene therapy. Patients with residual ABCB11 activity, however, may benefit from ABCB11 activation via chaperones in the future. Treatment of MDCK cells harboring a (E297G or D482G) mutant form of ABCB11 with 4-phenylbutyrate, for example, led to an increase in apical ABCB11 incorporation (Hayashi and Sugiyama, 2007). PFIC2 patients with residual ABCB11 activity are also more likely to benefit from UDCA, because tauroursodeoxycholic acid relies on a functional protein for its transport (Gerloff et al., 1998). UDCA shifts the bile acid pool to a more hydrophilic (i.e., less toxic) composition and promotes apical ABCB11 insertion (see below), which induces choleresis (Kurz et al., 2001; Dombrowski et al., 2006). Benign recurrent intrahepatic cholestasis 2 belongs to the same phenotypical continuum as ABCB11 and is characterized by mild and self-limiting episodes of cholestasis (Lam et al., 2006). Notably, ABCB11 knockout mice display a significantly milder phenotype compared with their human PFIC2 counterparts (Lam et al., 2005). This discrepancy could partly be attributed to the formation of less toxic polyhydroxylated bile acids in mice (Perwaiz et al., 2003). These hydrophilic bile acids could, in theory, be excreted via alternative hepatocellular bile acid transporters, such as ABCC2 and ABCB1.

The activity of ABCB11 is tightly regulated at the level of its transcription and by several posttranscriptional modifications. ABCB11 transcription is mainly regulated by FXR, as stated above. Other transcriptional factors, however, influenced the interaction of FXR with the ABCB11 promoter in vitro and in rodents. VDR activation, via 1,25-dihydroxyvitamin D3, inhibits FXR-induced ABCB11 transactivation (Honjo et al., 2006). Activating signal coactivator-2-containing complex recruitment by chenodeoxycholic acid increases FXR-induced transactivation, because this coactivator complex methylates the ABCB11 promoter histones (Ananthanarayanan et al., 2011). Steroid receptor coactivator-2 activation by liver kinase B1 and AMP-activated protein kinase also promotes FXR-induced transactivation by acetylation of promoter histones (Chopra et al., 2011). The liver receptor homolog-1 and the oxidative stress sensor nuclear factor erythroid 2–related factor 2 finally transactivate ABCB11 by binding to specific response elements in the ABCB11 promoter (Weerachayaphorn et al., 2009). The rapid, short-term, adaptation of canalicular ABCB11 expression can be mainly regulated at the posttranscriptional level. This regulation involves the shuttling of ABCB11 between its intracellular pool and the canalicular membrane and may be triggered by hormones (Crocez et al., 2003), oxidative stress (Pérez et al., 2006), hydration (Schmitt et al., 2001), and cell swelling (Häussinger et al., 1993), as demonstrated in vitro and in rodent studies. Cell swelling can occur in response to a meal and lead to a rapid canalicular insertion of ABCB11, which increases the postprandial excretion of bile acids. UDCA treatment, in addition, also increases bile flow partly via (post-transcriptional) canalicular ABCB11 insertion. The regulation of these posttranslational mechanisms involves the induction of integrins by cell swelling, which triggers focal adhesion kinase, proto-oncogene tyrosine-protein kinase, mitogen-activated protein kinase, and the oxidative stress sensor nuclear factor erythroid 2-related factor 2 finally transactivate ABCB11.

ABCC2

ABCC2 (multidrug resistance-associated protein 2) is expressed at critical sites of uptake and elimination and is involved in the excretion and detoxification of endo- and xenobiotics. Hepatic ABCC2 plays an important role in the canalicular excretion of glutathione and conjugated
bilirubin. ABCC2 mutations can cause the Dubin-Johnson-syndrome, which is characterized by a mild conjugated hyperbilirubinemia.

ABCC2 is a 190-kDa member of the C subfamily (ABCC) of ABC transporters. Its structure consists of two nucleotide-binding and three (instead of the normal two) transmembrane domains (Fig. 3). The function of the third transmembrane domain, which consists of 5 instead of 6 helices, is still being investigated (Fernández et al., 2002; Westlake et al., 2005). ABCC2 is expressed at the apical membrane of intestinal epithelial cells (Fromm et al., 2000; Sandusky et al., 2002), hepatocytes (Keppler and Kartenbeck, 1996), renal proximal tubule epithelial cells (Schau et al., 1997, 1999), gallbladder epithelial cells (Rost et al., 2001), and placental syncytiotrophoblast cells (Keppler, 2011b). This expression pattern at major barrier sites results in a decreased uptake (i.e., bioavailability) and an increased excretion of its various endo- and exogenous substrates. Although these mechanisms protect the body, they may also decrease treatment efficacy and/or lead to the development of multidrug resistance. The development of drug resistance, however, has mainly been associated with the overexpression of other multidrug transporters (i.e., ABCB1 and ABCG2) (Gerhard Ecker, 2009; Marquez and Van Bambeke, 2011).

ABCC2 transports various amphiphilic anions but displays a preference for phase II (e.g., glucuronic acid, sulfuric acid, or glutathione conjugated) metabolites (Table 1). Its endogenous substrates include tetrahydroxylated bile acids (Meganraj et al., 2010), divalent bile acids
et al., 2000) or positively charged (Cd^{2+} and Zn^{2+}) (Houwen et al., 2000). In addition, it transports uncharged (vinblastine, sulfinpyrazone) (Evers et al., 2000), anionic drugs, such as pravastatin (Yamazaki et al., 1997), ampicillin (Garzya et al., 2003a), bromosulfophthalein (Jansen et al., 1987), dinitrophenyl (Kuipers et al., 1988), glutathione (Oude Elferink et al., 1990), bilirubin (van der Wetering et al., 2007), or with glutathione [e.g., acetaminophen (Chen et al., 2000), morphine (van de Wetering et al., 2003), sulfuric acid [e.g., acetaminophen (Zamek-Gliszczynski et al., 2005), resveratrol (Kaldas et al., 2004)], or with glucuronic acid [e.g., phytoestrogens (Krumpochova et al., 2012), sulfuric acid (rs717620) (Daly et al., 2007). Several of these SNPs are also associated with altered pharmacokinetics of ABC22 substrate drugs, such as methotrexate and pravastatin. ABC22 polymorphisms also lead to a decreased biliary excretion of toxic metabolites during irinotecan treatment, which protects patients from irinotecan-induced diarrhea (de Jong et al., 2007; Gradhand and Kim, 2008; Megaraj et al., 2011).

ABC2 gene transcription is regulated by FXR, PXR, and CAR. These NRs heterodimerize with RXR after their activation and subsequently bind a shared 26-bp sequence hormone response element (ER-8) in the ABC22 promoter (Kast et al., 2002). FXR (e.g., chenodeoxycholic acid), PXR (e.g., rifampicin), and CAR (e.g., phenobarbital) agonists thus increased ABC22 expression in human and rodent livers (Fardel et al., 2005). Inflammatory cholestasis, sepsis, and obstructive cholestasis can decrease ABC22 expression by a cytokine-induced repression of transcriptional networks in vitro and in rodents (RARα, RXRa, FXR, PXR, CAR) (reviewed by Wagner et al., 2010). Bile duct ligation or lipopolysaccharide (LPS) treatment resulted in an IL-1β–mediated RARα/RXRa downregulation, which in turn decreased ABC22 transcription in rats (Denson et al., 2002). Oxidative stress (e.g., via toxic bile acids) can increase ABC22 transcription via nuclear factor erythroid 2–related factor 2 in rodents (Maher et al., 2007; Okada et al., 2008). Posttranscriptional modifications were associated with membrane retrieval and cytoplasmic accumulation of ABC22, which was indicated by a “fuzzy” immune-staining pattern. A similar fuzzy pattern was observed in cholestatic patients (e.g., in primary biliary cirrhosis and obstructive cholestasis) (Zollner et al., 2001; Kojima et al., 2003).

### ABCB1

ABCB1 (MDR1; MDR1a/MDR1b in rodents) protects the body from a broad variety of hydrophobic drugs and plays a key role in the development of multidrug resistance. ABCB1 also interacts with several biliary constituents (e.g., cholesterol, bile acids, phospholipids), but its contribution to bile formation and cholestasis remains to be established.

ABC1, a 170-kDa member of the B subfamily (ABC) of ABC transporters, consists of two nucleotide-binding and two 6-helical transmembrane domains (Fig. 3). ABC1 is expressed at the apical membrane of intestinal epithelial cells, hepatocytes, renal tubular epithelial cells, endothelial vascular cells of the blood-brain and blood-testis barriers, and in cells of the adrenal gland, pancreas, lung, and placenta (Thiebaut et al., 1987; Sugawara et al., 1988). This expression pattern allows ABC1 to inhibit the uptake of drugs from the intestinal lumen (bioavailability), decrease their entry in sanctuary organs, such as the brain and testes (distribution), and increase their renal and biliary elimination.

ABC1 is a highly promiscuous transporter that interacts with nearly half of all registered pharmaceutical compounds (Nicolaou et al., 2012). ABC1 transports mainly neutral or positively charged amphipathic compounds, although transport of negatively charged compounds (e.g., methotrexate) has been reported (Table 1) (de Graaf et al., 1996; Huang et al., 1998; Gerhard Ecker, 2009). Its unusual promiscuity has made it hard to find compounds that are not substrates. Accordingly, ABC1 has been implicated in the transport of various endogenous compounds, such as cholesterol (Lee et al., 2013), steroids [e.g., cortisol, aldosterone, ethinylestradiol, estrone, estriol (Ueda et al., 1992; Kim et al., 1998)].
and Benet, 2004)], short-chain (not long-chain) phospholipids (van Helvoort et al., 1996; Morita et al., 2007), opioid peptides (Oude Elferink and Zadina, 2001), unconjugated bilirubin (Jetté et al., 1995; Watchko et al., 2001), and tetrahydroxylated bile acids (Megaraj et al., 2010). Most of these compounds were only investigated in vitro and/or showed a low affinity for ABCB1. For several of these substrates (e.g., phospholipids, unconjugated bilirubin, tetrahydroxylated bile acids) it consequently remains to be determined if ABCB1 actually contributes to their in vivo metabolism. Exogenous ABCB1 substrates include chemotherapeutics [e.g., paclitaxel (Fellner et al., 2002), topotecan (Li et al., 2008), etoposide (Takeuchi et al., 2006), teniposide (Vasanathakumar and Ahmed, 1989), doxorubicin (Ueda et al., 1987), vincristine (Cisternino et al., 2001), vinblastine (Cisternino et al., 2001), daunorubcin (Takeuchi et al., 2006), docetaxel (Shirakawa et al., 1999), mitomycin C (Hayes et al., 2001)], cytotoxic drugs [e.g., colchicines (Cisternino et al., 2003)], antihypertensives [e.g., losartan (Soldner et al., 1999)] diltiazem (Katoh et al., 2006)], antiarrhythmics [e.g., verapamil (Soldner et al., 1999), digoxin (Pauli-Magnus et al., 2000)], antibiotics [e.g., erythromycin (Schuetz et al., 1998)], HIV-protease inhibitors [e.g., indinavir, ritonavir (Lee et al., 1998)], and various other xenobiotic compounds [rhodamine 123 (Bachmeier et al., 2005), Hoechst 33342 (Chen et al., 1993), calcein-AM (Holló et al., 1994)].

The physiologic function of ABCB1 has been extensively studied in mice. Mice possess, in contrast to humans, two genes that code for two ABCB1 proteins, namely ABCB1α and ABCB1β. Together, these proteins fulfill the same function as ABCB1 in humans. The deletion of these genes in mice did, somewhat surprisingly, not lead to a severe phenotype. ABCB1α/ABCB1β compound knockout mice were fertile, displayed a normal biliary composition and flow, and showed a normal life span under laboratory conditions. The absence of ABCB1α and ABCB1β, however, did result in an altered pharmacological profile of substrate drugs. This altered profile generally led to an increased bioavailability, an increased distribution volume (mainly to the brain), and a decreased renal/biliary elimination of ABCB1β substrates (Schinkel, 1998; Chen et al., 2003b). As a consequence, these animals displayed higher plasma and tissue (e.g., brain) levels of ABCB1α/β substrate drugs compared with their wild-type controls. Human ABCB1 mutations and polymorphisms have also been extensively investigated and were (similarly) not associated with any severe phenotype (reviewed by Lefèvre, 2012). ABCB1 SNPs did affect the pharmacokinetic profile of several drugs, but results were equivocal and differed significantly between studies. Consequently, ABCB1 genotype-directed drug dosing is not (yet) recommended in routine clinical practice (Wolf et al., 2011; Lefèvre, 2012). ABCB1 SNPs have also been associated with an increased susceptibility to various diseases, such as inflammatory bowel disease and colorectal cancer (Schwab et al., 2003; Andersen et al., 2009). The validity of these associations, however, remains to be established and deserves further investigation. The above-mentioned considerations do not infer that alterations in ABCB1 expression are of no consequence. Indeed, drug resistance that results from intrinsic (e.g., untreated) and acquired (e.g., drug-induced) ABCB1 overexpression remains a major problem in brain-targeted therapies and in anticancer treatment (Chen et al., 1991; Shukla et al., 2011). An increased expression of ABCB1 in tumor cells, for example, confers drug resistance by promoting the efflux of anticancer drugs (Gottsmann et al., 2002; Sikic, 2006). Indeed, ABCB1 tumor overexpression has been associated with nonresponse to chemotherapy and a poor clinical prognosis in various cancers (Chen et al., 1991; Penson et al., 2004; Sikic, 2006). These considerations led to the development of ABCB1 inhibitors, which overcame drug resistance in animal models and tumor cell lines. Unfortunately, these inhibitors remained unsuccessful in clinical trials because of side effects and toxicity (reviewed by Shukla et al., 2011; Falasca and Linton, 2012). This lack of success may be due to the complexity of multidrug transport, in which the inhibition of one transporter may lead to compensatory effects that can alter drug handling and promote toxicity.

The role of ABCB1 in bile formation and cholestasis has yet to be elucidated. Bile formation seems unaffected in ABCB1α/ABCB1β knockout mice, as discussed above. ABCB1 is, however, significantly upregulated in the liver of cholestatic animal models and in liver specimens of patients with obstructive cholestasis, biliary atresia, and primary biliary cirrhosis (PBC) (Schrenk et al., 1993; Shoda et al., 2001; Zollner et al., 2003; Barnes et al., 2007). The reason for this upregulation remains unclear, but it might result in an increased canicular excretion of toxins under cholestatic conditions. Interestingly, ABCB1α/β was shown to transport tetrahydroxylated bile acids in mice, albeit with a much lower affinity than ABCB2 (Megaraj et al., 2010). This transport could, as discussed in our section on ABCB11, mitigate the phenotype of ABCB11 knockout mice. This hypothesis was supported by the observation that 1) ABCB1 was markedly upregulated in ABCB11 knockout mice, and 2) that ABCB11/ABCB1α/ABCB1β compound knockout mice displayed a more severe cholestatic phenotype than single ABCB11 knockout (Wang et al., 2009b). ABCB1 may also protect hepatocytes against apoptosis under cholestatic conditions by exporting toxins (Sakaeda et al., 2002). Taken together, these observations support a compensatory role for ABCB1 during cholestasis. Its role in bile acid transport, however, is likely more important in mice than in humans, inasmuch as only mice are able to generate hydrophilic tetrahydroxylated bile acids as part of their adaptive response to cholestasis (Perwaiz et al., 2003).

ABCB1 transcription is mainly regulated via PXR, CAR, VDR, and FXR. PXR induced ABCB1 transcription in the intestine, liver, and kidney. Its agonists (e.g., rifampicin) consequently decreased the intestinal uptake (bioavailability) and increased the (biliary/renal) elimination of ABCB1 ligands in healthy volunteers (Chen, 2010). CAR agonists (e.g., CITCO [6-(4-chlorophenyl)-imidazo[2,1-b][1,3] thiazole-5-carbaldehyde]) induced ABCB1 expression in brain capillary cells (Chen, 2010; Lemmen et al., 2013). VDR activation, via 1,25-dihydroxyvitamin D3, induced ABCB1 in the kidney and brain of mice (Chow et al., 2011). Cholesterolcholic acid, a potent FXR agonist, induced ABCB1 expression in HepG2 cells (Martin et al., 2008). FXR knockout mice showed almost no increase in hepatic ABCB1 after bile duct ligation, which demonstrates that cholestatic upregulation of ABCB1 is largely FXR dependent in this animal model (Stedman et al., 2006). ABCB1 (post-) transcriptional regulation is certainly not the exclusive domain of these NRs. The tumor suppressor protein p53, for example, downregulates ABCB1α and ABCB1β and may influence drug resistance in cancer (Bush and Li, 2002). Rat ABCB1b is upregulated during endotoxin-induced cholestasis via tumor necrosis factor-α, which requires nuclear factor κB signaling (Ros et al., 2001). P53 actually increases ABCB1b and endotoxin treatment does not affect ABCB1α, which illustrates that the two rodent ABCB1 genes are differentially regulated. Indeed the (post-) transcriptional regulation of human ABCB1 is highly complex and influenced by epigenetic methylation, micro-RNA expression, and various other mechanisms (reviewed by Labialle et al., 2002; Baker and El-Osta, 2004; Toscano-Garibay and Aquino-Jarquin, 2012).

ABCG2

ABCG2 (breast cancer resistance protein) is the final canicular multidrug transporter that will be discussed in this review. Its main function is similar to that of ABCB2 and ABCB1, namely the
protection of the body against xenobiotics. ABCG2 does not seem to have a significant role in the adaptive response to cholestasis in the liver, although recent studies suggest that it is capable of bile acid transport. This transport, however, is likely more relevant in the placenta than in the liver.

ABCG2 is a 72-kDa member of the G subfamily (ABCG) of ABC transporters. Its structure consists of one N-terminal nucleotide-binding domain, and one C-terminal (6-helical) transmembrane domain (Fig. 5) (McDevitt et al., 2006; Ni et al., 2010). This structure is somewhat aberrant, because in most ABC transporters the transmembrane domain is located at the N-terminal end and the nucleotide-binding domain at the C-terminal end of the protein. ABCG2 is a half-transporter, like all members of the ABCG subfamily, and must at least dimerize to become functional. It is expressed at the apical membrane of intestinal epithelial cells (Gutmann et al., 2005), hepatocytes (Hilgendorf et al., 2007), renal tubular epithelial cells (Huls et al., 2008), endothelial vascular cells of the blood-brain and blood-testis barriers (Cooray et al., 2002; Fetsch et al., 2006), and cells of the placenta and mammary gland (Allikmets et al., 1998; Robey et al., 2011). Its expression pattern, at critical sites of uptake and elimination, resembles that of ABCB1. ABCG2 has consequently a similar effect on the bioavailability, distribution, and elimination of its ligands as ABCB1 (Vlaming et al., 2009; Agarwal et al., 2011). Because ABCG2 and ABCB1 are often colocalized and because they share many substrates, they can team up at critical barrier sites (Agarwal et al., 2011). This cooperation protects sanctuaries organs, such as the brain, but may also prevent entry of chemotherapeutic drugs, which can lead to treatment failure (e.g., in brain cancer) (Agarwal et al., 2011).

ABCG2 is, like ABCB1, somewhat promiscuous when it comes to its exogenous substrates. In addition, it has been shown in the transport of several endogenous compounds, including home (Jonker et al., 2002), porphyrins (Jonker et al., 2002), folates (mono- and di-glutamates of folic acid) (Lemos et al., 2009), urate (Woodward et al., 2009), sulfated steroids (Suzuki et al., 2003), and bile acids (Blazquez et al., 2012) (Table 1). Exogenous ABCG2 substrates include sulfuric acid [e.g., E3040S (Suzuki et al., 2003)], glucuronic acid [e.g., E3040G (Suzuki et al., 2003)], or glutathione-conjugated [e.g., dimethylphenyl glutathione (Suzuki et al., 2003)].

ABCG2 also transports various conjugated drugs, sometimes in cotransport with glutathione. It is, however, best known for its ability to transport chemotherapeutics, such as methotrexate (Chen et al., 2003c), topotecan (Maliepaard et al., 1999), mitoxantrone (Doyle et al., 1998), and the SN-38 metabolite of irinotecan (Maliepaard et al., 1999).

ABCG2 knockout mice did not, much like ABC2 and ABCB1a/b knockout mice, display a severe phenotype. This may well be because multidrug transporters have a considerable overlap in their substrates and sites of expression. If one gene is deleted, other transporters can compensate for its loss. A single gene deletion will therefore only have a limited phenotypic effect. ABCG2 knockout mice did accumulate endogenous (i.e., protoporphyrin X) and dietary (i.e., phophophorbid) porphyrins, which induced protoporphyria (via protoporphyrin X) and phototoxic skin lesions (via phophorbid) (Jonker et al., 2002). These mice also showed an increased bioavailability, an increased distribution volume (e.g., to the brain), and a decreased biliary/urinary elimination of ABCG2 substrate drugs (reviewed by Vlaming et al., 2009). ABCG2 gene mutations and polymorphisms were (similarly) not associated with a severe phenotype in humans. ABCG2 SNPs, however, were associated with an altered pharmacological profile of ABCG2 substrate drugs (e.g., sulfalazine, topotecan, statins) (reviewed by Ieiri, 2012). Interestingly, recent studies have demonstrated an association between ABCG2 SNPs (e.g., rs2231142) and the development of gout (Dehghan et al., 2008; Woodward et al., 2009).

These studies also identified uric acid as an ABCG2 substrate. ABCG2, like ABCB1, has been implicated to promote the efflux of anticancer drugs in tumor cell lines. Its role in drug resistance, however, remains to be established in a clinical setting, and clinical trials with ABCG2 inhibitors are currently not advisable (Falasca and Linton, 2012).

The role of ABCG2 in bile formation and cholestasis has been extensively debated. Mennone et al. (2010) failed to find a liver phenotype in bile duct-ligated or sham-operated ABCG2 knockout mice. This result pleaded against a significant role of hepatic ABCG2 in the adaptive response to cholestasis. A recent study in pregnant ABCG2 knockout mice by Blazquez et al. (2012), suggested that ABCG2 might affect bile acid transport in the placenta but not in the liver. This study also demonstrated bile acid transport by recombinant ABCG2 in WIF-B9/R cells, in Chinese hamster ovary cells, and in Xenopus laevis oocytes. Other in vitro studies have shown ABCG2-mediated bile acid transport in bacteria (Janvilliris et al., 2005), liver flukes (Iuukatake et al., 2008), and transfected plasma membrane vesicles (Inui et al., 2002). Some in vitro studies, however, failed to demonstrate a role of ABCG2 in bile acid transport (Suzuki et al., 2003; Vaidya and Gerk, 2006).

However, the majority of the available data from in vitro and animal studies suggests that ABCG2 is capable of bile acid transport. The importance of this transport may depend on the relative coexpression of other bile acid exporters (e.g., ABCB11, ABCB2) in the apical membrane (Mennone et al., 2010; Blazquez et al., 2012). The relative contribution of ABCG2 to bile acid transport will consequently be minimal in the liver because of the to the presence of ABCB11 (and ABCB2). Placental ABC2, however, has no (significant) coexpression of ABCB11 and may consequently play a major role in (local) bile acid transport (Patel et al., 2003).

ABCG2 transcription is regulated via CAR and PXR. CAR (phenobarbital, CITCO) and PXR (rifampicin and 2-acylaminofluorene) ligands can thus increase ABCG2 expression in vitro (Jigorel et al., 2006; Lemmen et al., 2013). Other transcription factors can also induce ABCG2, and its promoter contains hypoxia, estrogen, progesterone, PPARy, and aryl hydrocarbon receptor response elements (Ebert et al., 2005; Szatmari et al., 2006; Robey et al., 2011; To et al., 2011). Cytokines, growth factors, and micro-RNAs affected gene expression in various ways, whereas promoter methylation increased ABCG2 expression in vitro (Le Vee et al., 2009; Robey et al., 2011).

**ABCB4**

ABCB4 (MDR3; MDR2 in rodents) plays a key role in bile formation. Although ABCB11 transports bile acids, ABCB4 secretes phosphatidylcholine (PC). PC and cholesterol form mixed stable micelles with bile acids, which protect the biliary tree from their detergent effects.

ABCB4, a 170-kDa member of the B subfamily (ABC) of ABC transporters, consists of two nucleotide-binding and two 6-helical transmembrane domains (Fig. 3) (Zhang, 1996). ABCB4 is predominantly expressed in the apical membrane of hepatocytes (Yoshikado et al., 2011; Pasman et al., 2012), although low levels of mRNA transcripts have been detected in the adrenal glands, heart, striated muscles, tonsils, placenta, and brain (Smit et al., 1994; Patel et al., 2003; Augustine et al., 2005; Kim et al., 2008; Cui et al., 2009). This expression pattern supports its role as the major canalicular PC transporter in humans. ABCB4, a so-called floppase, translocates ("flops") PC from the inner to the outer leaflet of the canalicular membrane, from where it is extracted by bile acids (Smit et al., 1993). The association of PC with bile acids (and cholesterol) results in the
formation of mixed and stable micelles (Wang et al., 2009a). These micelles protect the epithelial lining of the biliary tree from bile acid–induced toxicity and phospholipid extraction (reviewed by Trauner et al., 2008). Although ABCB4 is a particularly specific PC transporter, it has a weak affinity for some ABCB1 substrate drugs (e.g., digoxin, paclitaxel, vinblastine; Table 1) (Smith et al., 2000). The clinical relevance of this transport, however, has not been established. Other drugs, such as oral contraceptives and itraconazole, can inhibit ABCB4 activity, which may result in drug-induced liver damage (Yoshikado et al., 2011; Pasmand et al., 2012).

A loss in ABCB4 function is not readily compensated and leads to severe hepatobiliary pathology in animal models and patients. ABCB4 knockout mice are unable to excrete PC and consequently produce toxic bile. This toxicity is due to the relatively high nonmicellar (“free”) bile acid concentration and leads to an increased permeability of the biliary epithelium, bile leakage, pericholangitis, periductal fibrosis, sclerosing cholangitis, and finally (in older mice) to hepatocellular carcinoma (Mauad et al., 1994; Fickert et al., 2002, 2004; Katzenellenbogen et al., 2007). The impaired PC/bile acid micelle formation also decreases the canalicular excretion (i.e., secretion) and solubility of cholesterol. The latter results in the recurrent formation of cholesterol gallstones (Trauner et al., 2008). Patients with progressive familial intrahepatic cholestasis type 3 (PFIC3) are the human counterparts of ABCB4 knockout mice. PFIC3 usually has a similar clinical presentation as PFIC2 (see ABCB11 section) but may also present with recurrent choledocholithiasis in older children and adults (reviewed by Jacquemin, 2012). Although UDCA treatment can be helpful in the presence of a partial ABCB4 defect, hepatic transplantation will remain the only definitive therapy before gene therapy becomes available in most patients (Deleuze et al., 1996; De Vree et al., 1998). Patients with misfolding of the transporter, such as the reported PFIC3 heterozygous mutation I541F, may benefit from chaperone treatment to correct these folding defects in the future (Delanay et al., 2009; Gautheron et al., 2012). Cyclosporine A was indeed able to restore a correct maturation of the endoplasmic reticulum sequestered I541F mutant in vitro (Gautheron et al., 2012). Less severe ABCB4 mutations can lead to the low phospholipid associated cholelithiasis syndrome (LPAC) and intrahepatic cholestasis of pregnancy (ICP). LPAC is characterized by the formation of cholesterol gallstones and may lead to progressive fibrosing cholestatic liver disease and portal hypertension (Zakim et al., 2011). ICP usually manifests in the second or third trimester of pregnancy and is associated with itching, abnormal liver biochemistry, and jaundice. Although it usually resolves spontaneously after delivery, it is associated with fetal risk (e.g., prematurity, neonatal respiratory distress syndrome) (Dixon et al., 2000). Both LPAC and ICP are treated with UDCA, which prevents gallstone formation in LPAC and improves symptoms and liver biochemistry in ICP. Bile duct ligation or partial hepatectomy only slightly enhanced ABCB4 expression in mice (Stedman et al., 2006; Csakny et al., 2009), whereas TPN decreased ABCB4 expression in rats (Nishimura et al., 2005). Several other cellular stress conditions (e.g., endotoxin treatment) were not associated with an altered ABCB4 expression in animal studies (Vos et al., 1998).

ABCB4 regulation is still poorly understood but occurs partly via FXR and PPARα. FXR agonists (cholate, GW4064) transactivate the human ABCB4 gene in vitro, which results in an increased maximal biliary PC secretion (Huang et al., 2003a). FXR thus regulates both biliary bile acid (ABCB11) and phospholipid (ABCB4) excretion. PPARα agonists (fibrates) also increased ABCB4 expression in human hepatocytes (Ghonom et al., 2012).

**ABCG5/8**

ABCG5/8 is the main sterol transporter and plays a key role in the biliary excretion of cholesterol and plant sterols (i.e., phytosterols). Mutations in the *ABCG5* or *ABCG8* gene lead to the development of sitosterolemia, which is characterized by sterol accumulation and atherosclerosis.

ABCG5 (73 kDa) and ABCG8 (76 kDa) are both members of the G subfamily of ABC transporters. Members of this transporter family are half transporters as mentioned in our section on ABCG2. ABCG5 and G8, which each consist of one nucleotide-binding and one 6-helical transmembrane domain, consequently need to combine to become functional (Fig. 3) (Graf et al., 2002). The ABCG5/8 heterodimer transports sterols (i.e., phytosterols and cholesterol; Table 1) and is expressed in the apical membrane of hepatocytes and enterocytes (Berge et al., 2000). This expression pattern allows ABCG5/8 to promote sterol excretion in the bile and to prevent sterol uptake from the intestinal lumen. ABCG5/8 knockout mice displayed a 75% decrease in biliary cholesterol excretion, which showed a large but not exclusive role for ABCG5/8 in biliary cholesterol transport (the remaining 25% was partly transported by canalicular scavenger receptor B1) (Yu et al., 2002a; Klett et al., 2004; Wiersma et al., 2009; Dikkers et al., 2013). These mice do not display a severe cholestatic phenotype like ABCB4 knockout mice, which indicates that mixed micelle formation remains adequate in the absence of this transporter (Yu et al., 2002a; Klett et al., 2004; Wiersma et al., 2009; Dikkers et al., 2013). Other studies in mice showed that ABCG5/8 overexpression protected against atherosclerosis. This protective effect was only present in mice that overexpressed this transporter both in the biliary canaliculus and in the intestine, which illustrated the complementary effect of canalicular and intestinal ABCG5/8-mediated sterol transport (Yu et al., 2002b; Wilund et al., 2004). The role of ABCG5/8 in sterol transport was first discovered in sitosterolemia, which is characterized by an increased dietary absorption and a decreased biliary excretion of sterols (Berge et al., 2000; Lee et al., 2001). Patients with this rare inherited disease consequently accumulate phytosterols (e.g., sitosterol, stigmasterol, campesterol, 5α cholesterol, 5α-campestanol, 5α-sitostanol, 22-dehydrocholesterol, brassicasterol, and 24-methylene cholesterol) and cholesterol in their blood and suffer from premature development of atherosclerosis (Berger et al., 2000). Because sitosterolemia is caused by mutations in the *ABCG5* or *ABCG8* gene, it was concluded that cholesterol and the above-mentioned plant sterols are ABCG5/G8 substrates. ABCG5/8 polymorphisms, such as the common SNP rs11887534, also increase the risk of cholesterol gallstones (and lead to obstructive cholestasis), likely by increasing the biliary cholesterol content (Grünhage et al., 2007). Apart from its role in gallstone formation, ABCG5/8 does not seem to be a major contributor to cholestatic disease, as illustrated by the absence of a cholestatic phenotype in ABCG5/8 knockout mice and sitosterolemia patients.

ABCG5/8 transcription is mainly regulated via the liver X receptor (LXR) and FXR (Janowski et al., 1996; Lehmann et al., 1997; Janowski et al., 1999; Gupta et al., 2002; Freeman et al., 2004). LXR is activated by oxysterols and promotes sterol excretion (ABCG5/8) and the conversion of cholesterol into bile acids (CYP7A1) in rodents (Gupta et al., 2002). FXR inhibits liver receptor homolog-1 (via SHP), which decreases ABCG5/8 expression in human liver and intestinal cell lines (Freeman et al., 2004). FXR also inhibits CYP7A1 and CYP5B1, which leads to a reduced bile acid synthesis (Gupta et al., 2002). FXR and LXR thus have opposite effects on ABCG5/8 and bile acid synthesis. Several other transcription factors also play a role in ABCG5/8 transactivation. GATA-binding protein 4 (GATA4), GATA6, and hepatocyte nuclear factor 4-α synergistically induce human ABCG5/8.
transcription in vitro (Sumi et al., 2007). Thyroid hormone also increased biliary cholesterol excretion in animal models by increasing ABCG5/8 expression, although the exact mechanism remains to be elucidated (Gälman et al., 2008; Bonde et al., 2012). Treatment with thyroid hormone and its liver specific agonists (e.g., eprotirome, sobetirome) significantly lowered cholesterol in various animal models, although its use in humans will be limited because of potential side effects and the safety and efficacy of statin treatment. Insulin resistance can, finally, increase ABCG5/8 expression in mice via disinhibition of the forkhead box O1A transcription factor by insulin (Biddinger et al., 2008).

Canalicular ABC Transporters and Their Regulatory NRs as Drug Targets

Canalicular ABC transporters and their NRs play a key role in bile formation and cholestasis. As such they are attractive targets for the treatment of cholestatic disease. We will therefore briefly discuss the effect of several important (experimental) treatment strategies on their expression.

UDCA, the only Food and Drug Administration–approved drug for cholestasis, promoted the canalicular insertion of ABCB11, ABCB2, and ABCB4 in rodents (Beuers et al., 2001; Fickert et al., 2001; Kurz et al., 2001). This posttranscriptional modification stimulated bile flow (ABCB11, ABCB2) and promoted the excretion of various biliary constituents (e.g., bile acids, glutathione, phospholipids) (reviewed by Poupon, 2012). Although UDCA has limited transcriptional effects, it also acts as a weak FXR and (after intestinal conversion to lithocholic acid) PXR agonist in vitro and in animal studies (Staudinger et al., 2001; Lew et al., 2004). The activation of these NRs increased the canalicular (e.g., ABCB11, ABCB2) and basolateral (e.g., ABC3, ABC4) expression of bile acid exporters (reviewed by Poupon, 2012; Halilbasic et al., 2013). UDCA has, in addition, various other beneficial effects, such as increasing the hydrophilicity of the circulating bile acid pool, cytoprotection against bile acids and cytokines, immune modulation, and anti-inflammatory effects (reviewed by Poupon, 2012). In PBC patients, UDCA combined with budesonide (but not UDCA or budesonide alone) restored the activity of cholangiocyte anion exchanger 2, which mitigated the impaired cholestasis in these patients (Arenas et al., 2008). UDCA also induced the antimicrobial peptide cathelicidin in PBC patients, presumably via VDR activation (D’Aldebert et al., 2009).

The development of norUDCA, a side chain shortened UDCA analog, represents a promising new treatment strategy for cholestatic bile duct diseases. NorUDCA does not exert its primary therapeutic effects via canalicular ABC transporters, although it did increase ABCB11 activity in vitro (Kagawa et al., 2013). Nevertheless, it almost completely reversed sclerosing cholangitis in the ABCB4 knockout mouse model for PBC (Fickert et al., 2006). Its suggested therapeutic mechanisms include an increased hydrophilicity of the circulating bile acid pool, protection of injured bile ducts by a bicarbonate-rich cholestasis, a decreased hepatocellular bile acid load by the induction of basolateral bile acid efflux transporters and bile acid detoxification pathways (phase I and II enzymes), and various anti-inflammatory and antifibrotic properties (reviewed by Trauner et al., 2008). NorUDCA supposedly has an intrinsic capacity to undergo cholehepatic shunting, which is essential for several of its beneficial effects (e.g., biliary HCO3⁻ output) (Halilbasic et al., 2009). The above-mentioned beneficial effects clearly favor its therapeutic potential, and norUDCA treatment is currently being evaluated in PBC and PSC patients.

The past years have witnessed the development of several synthetic FXR activators. These activators have a far higher affinity for FXR than natural bile acids and can be either bile acid- or non-bile acid-derived. The hepatoprotective effects of these activators have been convincingly demonstrated in animal studies. FXR activation in rodents promoted bile formation via ABCB11, ABCB2, ABCB1, and ABCB4. FXR also repressed hepatocellular bile acid uptake and synthesis and promoted bile acid elimination and detoxification, as discussed in our section on bile acid metabolism. GW4064, a non-bile acid-based FXR activator, and 6E-chenodeoxycholic acid (INT747), a synthetic bile acid analog, ameliorated obstructive and chemically induced cholestasis in rats (Liu et al., 2003; Fiorucci et al., 2005). INT767, another synthetic bile acid analog, mitigated biliary fibrosis and portal inflammation in the ABCB4 knockout mouse. INT767 increased, among others, the biliary bicarbonate content in these animals, which decreased biliary toxicity (Baghdasaryan et al., 2011). FXR activation also has anti-inflammatory properties, because chenodeoxycholic acid treatment induced the expression of the antimicrobial peptide cathelicidin in the human biliary epithelium (D’Aldebert et al., 2009). Finally, FXR activation via GW4064 counteracted bacterial overgrowth in bile duct–ligated rodents (Ogata et al., 2003). FXR activation thus promotes bile formation, decreases the hepatocellular bile acid load, decreases biliary toxicity, and has anti-inflammatory and antimicrobial effects. In recent phase II clinical trials, INT747 with or without UDCA cotreatment ameliorated the biochemical markers of liver damage in PBC patients that were nonresponsive to UDCA alone. Results of a multicenter INT747 trial in UDCA-responsive PBC patients are currently awaited (Mason et al., 2010; Hirschfield et al., 2011; Kowdle et al., 2011).

FXR and CAR induce bile acid detoxification, bile acid elimination, and bilirubin glucuronidation, as discussed in our section on bile acid metabolism. Several PXR and CAR ligands have been used to treat pruritus or jaundice long before their mode of action became known. Rifampicin, a classic PXR agonist, is used to treat pruritus in cholestatic patients and ameliorated biochemical markers of liver damage in PBC patients (Bachs et al., 1989; Cançado et al., 1998; Yerushalmi et al., 1999). Rifampicin induced bile acid and bilirubin elimination via canalicular ABC2C. In addition, it induced bile acid detoxification (CYP3A4) and bilirubin conjugation (UGT1A1) in rodents (Marschall et al., 2005). Its antipuritic effect may partly involve PXR-mediated transactivation of autotaxin, a recently identified mediator of pruritus (Kremer et al., 2012). Phenobarbital, a potent CAR agonist, was used to treat neonatal jaundice in the 1960s and exerts its hypobilirubinemic effect by inducing ABC2C and UGT1A1 (reviewed by Cuperus et al., 2009).

PPARs, finally, are fatty acid–activated NRs that play an important role in lipid homeostasis. These NRs, however, also play a role in bile formation and cholestasis. Treatment with the PPARγ agonist fenofibrate increased the canalicular expression of ABCB4 in human hepatoma cells, which may be beneficial in patients with inherited ABCB4 defects (i.e., PFIC3, LPAC, and ICP) (Ghobem et al., 2012). In addition, PPARγ decreased bile acid synthesis (CYP7A1) and induced bile acid detoxification (SULT2A1, UGT2B4, UGT1A3) in animal models (Patel et al., 2000; Jung et al., 2002; Barrier et al., 2003; Fang et al., 2005). The PPAR agonist bezafibrate showed beneficial effects in PBC patients in pilot trials, although these results need to be confirmed by larger randomized-controlled clinical trials (Honda et al., 2013).

Conclusion and Perspectives

Canalicular ABC transporters and their regulatory transporters play a key role in the pathogenesis and pathophysiology of cholestatic disorders. The study of these transporters has provided researchers and
clinicians with a molecular framework that allows the development of novel treatment strategies. The clinical implementation of some of these treatments (e.g., FXR agonists, norUDCA) will likely benefit cholestatic patients in the near future.
