ABSTRACT

Nonalcoholic fatty liver disease (NAFLD) is the leading cause of liver disease in the Western world, given its association with obesity, type 2 diabetes, and dyslipidemia. Medications are widely used in NAFLD to manage comorbid conditions, and there is significant interest in developing new drug therapies to treat the disease. Despite this, little is known about the effects of NAFLD on drug metabolism. We examined the activity and expression of the major drug-metabolizing enzyme subfamily, CYP3A, in subjects with NAFLD as well as in mouse and cellular models. CYP3A activity was determined in healthy volunteers and subjects with biopsy-proven NAFLD by oral midazolam phenotyping and measurement of plasma 4β-hydroxycholesterol, an endogenous metabolic biomarker. CYP3A4 transcriptional activity, metabolic activity, and expression were also assessed in a mouse and cellular model of NAFLD. Subjects with nonalcoholic steatohepatitis (NASH) had 2.4-fold higher plasma midazolam levels compared with controls. Plasma 4β-hydroxycholesterol was 51% and 37% lower than controls in subjects with simple steatosis and NASH, respectively. Fibrosis was associated with 57% lower plasma 4β-hydroxycholesterol levels than controls. Furthermore, hepatic CYP3A4 mRNA expression in NASH was 69% lower than control livers. CYP3A4 gene luciferase activity in the livers of NAFLD mice was 38% lower than that of controls. Lipid-loaded HuH7 human hepatoma cells had a 38% reduction in CYP3A4 activity and 80% lower CYP3A4 mRNA expression compared with the control. CYP3A activity is reduced in human NAFLD in addition to mouse and in vitro cell models of the disease.

Introduction

Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease in the Western world, affecting 20%–35% of the general adult population and 70%–90% of obese individuals (Browning et al., 2004; Bedogni et al., 2005). Given its close association with the metabolic syndrome and increased risk of cardiovascular disease, many NAFLD patients are prescribed a variety of medications to manage these associated conditions (Stepanova and Yoonossi, 2012). Although the liver is the primary site of drug metabolism, little is known about the effect of NAFLD on this process. With the current lack of approved pharmacologic treatments for NAFLD, much of the current focus of therapy for this condition has been in managing comorbid conditions. If significant differences in drug metabolism are present in NAFLD, this may have implications not only for dosing and administration of currently used medications but also for the development of new therapies targeting hepatic steatosis and fibrosis.

There is a paucity of information on the influence of NAFLD on the in vivo activity of major hepatic drug-metabolizing pathways. A key pathway involves CYP3A enzymes (CYP3A4 and CYP3A5), which act in the intestine and liver. CYP3A4 is responsible for the oxidative metabolism of more than 50% of all drugs, including those widely prescribed in NAFLD such as 3-hydroxy-3-methylglutaryl-CoA reductase inhibitors (statins), calcium channel blockers, thiazolidinediones, and sulfonylureas (Guengerich, 1999). Intersubject variability in hepatic CYP3A enzyme activity can reach 100-fold (Lin and Lu, 2001). This highly variable enzyme activity has been largely attributed to environmental factors (Burk and Wojnowski, 2004; Wilkinson, 2005) and genetic polymorphisms including reduced activity CYP3A4*22 (Wang et al., 2011) and the inactivating allele CYP3A5*3 (Kuehl et al., 2001).

In the setting of cirrhosis, there is clear in vivo evidence for reduced hepatic CYP3A activity, which contributes to decreased drug dose requirements (Verbeek, 2008). However, in NAFLD with simple steatosis (SS) and nonalcoholic steatohepatitis (NASH), in vivo CYP3A activity has not been evaluated. A small number of ex vivo studies using archived livers have been published but findings are conflicting, reporting increased (Niemeli et al., 2000), decreased (Donato et al., 2006, 2007), or unchanged (Kolwankar et al., 2007; Fisher et al., 2009) hepatic CYP3A4 protein expression in NAFLD. Moreover, those studies that noted decreased CYP3A4 protein expression differed with respect to whether CYP3A4 mRNA was also reduced (Niemeli et al., 2000; Fisher et al., 2009). In a study of donated human type 2 diabetic liver, where NAFLD has a prevalence of 50%, hepatic CYP3A4 expression was reduced (Dostalek et al., 2011). Taken together, a majority of studies to date suggest that NAFLD is associated with reduced hepatic CYP3A3 activity; however, the data are heterogeneous and this finding has not yet been demonstrated in vivo.

In this study, we directly examined CYP3A drug metabolism activity in patients with biopsy-proven NAFLD as well as in both mouse and human NAFLD.
cell culture models of hepatic steatosis. We demonstrate, for the first time, that in vivo CYP3A activity is decreased in NAFLD.

Materials and Methods

In Vivo CYP3A Activity Phenotyping. The short-acting benzodiazepine, midazolam (MDZ), is oxidatively metabolized by CYP3A4 and CYP3A5 (Gorski et al., 1994). MDZ pharmacokinetic phenotyping is a widely used method to assess in vivo CYP3A activity (Lin et al., 2001). After an overnight fast, a group of 10 subjects with biopsy-proven NAFLD and a cohort of 20 healthy control subjects collected from previous studies reported by Woolsey et al. (submitted) and Gong et al. (2012) received an oral microdose (100 μg) of MDZ (1 mg/ml; Sanofi, Boucherville, Quebec, Canada) as an aqueous solution. Blood was collected 3 hours after drug administration for plasma MDZ concentration analysis. 4β-Hydroxycholesterol (4β-OH) is a cholesterol metabolite formed by CYP3A4/CYP3A5 and is an endogenous biomarker for in vivo CYP3A activity (Diczfalusy et al., 2011). Fasting plasma was obtained from the healthy control subjects (n = 20) and subjects with biopsy-proven NAFLD (n = 30) for 4β-OH level analysis. Histologic NAFLD stage was categorized as SS or NASH, according to the nonalcoholic fatty liver disease activity score (NAS), which includes steatosis (0–3), hepatic inflammation (0–3), and hepatocellular ballooning (0–2). Patients were categorized as having NASH if their NAS was ≥ 3 with a ballooning score of ≥ 1. SS was determined as total NAS of < 3 or ≤ 3 with a ballooning score of 0. Hepatic fibrosis was scored separately (0–4) (no fibrosis = 0 and fibrosis = 1). Insulin resistance was calculated using the homeostasis model assessment of insulin resistance (HOMA IR). These studies conformed to the ethical guidelines of the 1975 Declaration of Helsinki and were approved by the Human Subjects Research Ethics Board at the University of Western Ontario. All study participants provided informed written consent.

Genotyping. Single nucleotide polymorphisms associated with altered CYP3A activity were genotyped by TaqMan allelic discrimination assay (Applied Biosystems, Foster City, CA) for CYP3A4*22 (rs35599367), CYP3A5*3 (rs776746), peroxisome proliferator activating receptor α (Ppara, rs54235728), and cytochrome P450 oxidoreductase POR (rs1057868). Patatin-like phospholipase domain-containing protein 3 (PNPLA3, rs738409) gene variation associated with hepatic steatosis was similarly determined.

Human Liver Tissues. Liver samples used for gene expression (mRNA) analyses were obtained by biopsy from subjects with NAFLD (n = 17; mean age 46 years; 10 men, 7 women; 3 SS, 14 NAS) as reported by Beaton et al. (2013), whereas normal human liver samples (n = 9; mean age 45 years; 3 men, 6 women) were obtained through the Liver Tissue Cell Distribution System (Minneapolis, MN; funded by National Institutes of Health Contract N01DK70004/HHSN270200700004C). Control livers were chosen as those without hepatic steatosis after Oil Red O histologic staining.

Drug, Metabolite, and Endogenous Biomarker Analysis. Plasma and samples from each cell culture study were analyzed for levels of MDZ and its CYP3A-catalyzed primary metabolite, 1-hydroxyxymidazolam, by liquid chromatography–tandem mass spectrometry (LC-MS/MS) according to our previous report (Woolsey et al., submitted). 4β-OH levels in plasma were measured after picolinic acid derivatization and LC-MS/MS analysis according to the method of Honda et al. (2010) and detailed in our previous report (Woolsey et al., submitted). Statistical Analysis. Expression values are expressed as means ± S.E.M. or Tukey box plots. Differences between experimental groups were evaluated using an unpaired, two-tailed t test or a one-way analysis of variance with the Dunnett test. Differences were considered significant at the P < 0.05 level. All analysis was performed using GraphPad Prism software (version 5.0; GraphPad Software Inc., La Jolla, CA).

Results

CYP3A Activity and Expression Are Decreased in NAFLD. We examined in vivo CYP3A activity using oral MDZ phenotyping and plasma 4β-OH biomarker level analysis. Control subjects (n = 20) were tested with both MDZ and 4β-OH tests. MDZ phenotyping and 4β-OH plasma level was determined in 10 and 30 subjects with biopsy-proven NAFLD, respectively. Subject demographics are summarized in Table 1. Neither healthy control nor NAFLD study subjects were taking CYP3A4-interacting medications at the time of study participation (Supplemental Tables 1 and 2). All NAFLD subjects and 17 of 20 control subjects consented to genetic analysis. There were no significant differences in the frequencies of allele carriers associated with CYP3A activity, MDZ pharmacokinetics, or plasma 4β-OH levels among study groups (Table 1). We found that mean MDZ concentrations were 2.4-fold greater (P < 0.0001) in subjects with NASH (n = 9) compared with control subjects (Fig. 1A). The single subject with SS had 2.5-fold higher MDZ levels than controls (Fig. 1A). This result suggests that MDZ was not as readily metabolized in NASH...

aNASH was defined as an NAS [steatosis (0–3), lobular inflammation (0–3), and hepatocellular ballooning (0–2)] ≥3 plus a hepatocellular ballooning score ≥1. SS was defined as an NAS <3 or an NAS ≤3 with a ballooning score of 0.
bDegree of fibrosis was categorized by histologic fibrosis score (0–4; no fibrosis = 0 and fibrosis = ≥1).
cNumber of noncarriers/heterozygous carriers/homozygous carriers. For the control group, genotype was available for 17 of 20 subjects.

due to a decrease in CYP3A activity. NAFLD and healthy control subjects were also phenotyped for CYP3A activity using fasting plasma 4β-OHC level. NAFLD subjects had significantly lower mean 4β-OHC levels compared with control subjects (SS: 51% lower than control, P < 0.001; NASH: 37% lower than control, P < 0.001) (Fig. 1B), indicating decreased CYP3A activity. We separately examined the influence of hepatic fibrosis, PNPLA3 genotype, and HOMA IR on plasma 4β-OHC levels. There were lower 4β-OHC levels compared with control subjects (SS: 51% lower than control, P < 0.001; NASH: 37% lower than control, P < 0.001) (Fig. 1B), indicating decreased CYP3A activity. Furthermore, insulin resistance, as assessed by HOMA IR, was not associated with plasma 4β-OHC levels among participants with NAFLD (Supplemental Fig. 1B). CYP3A4 mRNA levels were 69% lower in NASH biopsies (n = 14) than in control livers (n = 9; P = 0.059) (Fig. 1D). The amount of CYP3A4 mRNA was 60% lower in biopsies with SS (n = 3) than in control livers (n = 9); however, this difference was not statistically significant (P = 0.34) (Fig. 1D). In composite, results from both the MDZ and 4β-OHC phenotyping tests demonstrate that in vivo CYP3A activity is reduced in NAFLD. Fibrosis is associated with lower CYP3A enzyme function. Reduced in vivo CYP3A activity is associated with decreased hepatic CYP3A4 mRNA levels.
Reduced CYP3A4 Transcriptional Activity in a Mouse Model of NAFLD. Female C57BL/6 mice were fed a high-fat diet for 4 weeks to induce NAFLD. SS was observed after hematoxylin and eosin, trichrome, and Oil Red O lipid staining of livers of mice fed a high-fat diet, whereas steatosis was absent in animals fed a normal diet (Fig. 2A). The livers of mice were in vivo transfected with a CYP3A4-XREM-Luc reporter plasmid or a pGL3 Basic control plasmid in conjunction with a normalizing Renilla luciferase vector, by the hydrodynamic tail-vein injection method. Hepatic CYP3A4 luciferase activity in the NAFLD mouse model was lower by 60% compared with mice on a normal diet (Fig. 2B). These results demonstrate that hepatic steatosis causes reduced liver CYP3A4 transcriptional activity in an in vivo model of NAFLD.

CYP3A4 Activity and Expression Are Decreased in a NAFLD Cell Culture Model. Huh7 human hepatoma cells were incubated with and without fatty acids to induce steatosis. Lipid accumulation was confirmed using the neutral lipid stain, Nile red (Fig. 3, A and B). The fatty acid treatment did not cause cytotoxicity up to concentrations of 600 µM, as determined by the MTT assay (Supplemental Fig. 2). Incubation of cells with MDZ (1 µg/ml) resulted in the appearance of the CYP3A metabolite, 1-hydroxymidazolam, in the culture media. The levels of 1-hydroxymidazolam in the fatty acid–treated Huh7 cells were lower by 38% compared with control cells (Fig. 3C), indicating reduced CYP3A3 enzyme activity in experimental steatosis. Furthermore, there was a significant decrease (reduction of 80%) in CYP3A4 mRNA expression in steatotic cells compared with control cells (Fig. 3D). These findings indicate that steatosis is associated with a reduction in CYP3A4 mRNA expression, leading to decreased enzyme activity in a cell culture model of NAFLD.

Discussion

With the global prevalence of NAFLD rising (Loomba and Sanyal, 2013), it is expected that this disease will become the number one indication for liver transplantation (Charlton et al., 2011). As such, the need for effective drug therapy to prevent disease progression is vital. Unfortunately, little is known about the effect of NAFLD on drug metabolism capacity, oral bioavailability, systemic exposure, and therapeutic response. The strongest evidence supporting altered drug metabolism relates to the well characterized induction of hepatic CYP2E1 expression and in vivo activity in NAFLD (Chalasani et al., 2003; Emery et al., 2003). CYP2E1 induction has been associated with enhanced susceptibility to acetaminophen bioactivation (to its reactive metabolite) and hepatotoxicity (Michaut et al., 2014). In this study, we also observed significantly increased CYP2E1 mRNA expression in both human NAFLD subjects and the cell culture model. In the mouse model of NAFLD, a trend toward an increased Cyp2e1 mRNA level was observed (Supplemental Fig. 3). Although there is evidence for CYP2E1 alterations in NAFLD, whether the expression and activity of the CYP3A subfamily is affected by NAFLD is not as clear. The in vivo activity of these primary drug-metabolizing enzymes in NAFLD has not been previously reported. In this study, we demonstrate that subjects with biopsy-proven NAFLD, phenotyped using an oral microdose of MDZ, have increased plasma MDZ concentrations compared with healthy control subjects (Fig. 1A). The validity of this simplified microdose and single-time-point sampling phenotyping strategy is supported by pharmacokinetic linearity of MDZ over a wide oral dose range (Halama et al., 2013) as well as a strong correlation between the 3-hour plasma concentration with area under the concentration-time curve (Lin et al., 2001; Woolsey et al., submitted). The observed 2.4-fold higher midazolam exposure in NAS compared with healthy subjects indicates moderately reduced CYP3A activity, given that the drug interaction with the potent CYP3A inhibitor ketoconazole results in a 16-fold increase in the oral midazolam area under the curve (Tsunoda et al., 1999).

We further assessed in vivo CYP3A activity by measuring plasma concentrations of 4β-OH, a product of CYP3A-mediated metabolism of cholesterol (Diczfalusy et al., 2011). NAFLD patients had significantly lower 4β-OH levels than controls, again indicating a decrease in CYP3A activity (Fig. 1B). Interestingly, CYP3A4 activity did not differ between NAFLD subjects with SS or NASH (P = 0.4941), despite studies demonstrating marked reduction in CYP3A4 expression and metabolic function in cultured human hepatocytes treated with inflammatory cytokines (Abdel-Razzak et al., 1993; Muntané-Relat et al., 1995). When examined independently from NAS, fibrosis, a marker of advanced NAFLD, was associated with significantly lower 4β-OH levels compared with the control.

Plasma 4β-OH levels are sensitive to the effects of CYP3A4 induction by drugs such as anticonvulsants (Bodin et al., 2001). However, the use of 4β-OH as a biomarker for decreased CYP3A4 activity by enzyme inhibition with drugs may be limited due to the long half-life of this oxysterol, requiring weeks of inhibitor administration.
for reductions in plasma levels to become apparent (Josephson et al., 2008). In the context of disease effects on CYP3A4 activity, our results in NAFLD, as well as those reported for Crohn’s disease (Iwamoto et al., 2013), show that 4β-OHC may be a valid biomarker of reduced metabolic activity for chronic conditions. Plasma 4β-OHC levels are a reflection of CYP3A4 activity in the liver, as was demonstrated in a study of subjects treated with the enzyme inducer efavirenz (Meyer zu Schwabedissen et al., 2012). Systemic levels of this biomarker were increased, whereas no changes in intestinal CYP3A4 expression were observed. Our results implicate changes in liver CYP3A4 levels; however, the contribution of intestinal CYP3A4 expression were observed.

Our results implicate changes in this biomarker were increased, whereas no changes in intestinal efavirenz (Meyer zu Schwabedissen et al., 2012). Systemic levels of demonstrated in a study of subjects treated with the enzyme inducer efavirenz (Meyer zu Schwabedissen et al., 2012). Systemic levels of this biomarker were increased, whereas no changes in intestinal CYP3A4 expression were observed. Our results implicate changes in liver CYP3A4 levels; however, the contribution of intestinal CYP3A4 expression to plasma 4β-OHC concentrations in NAFLD has not yet been formally evaluated.

There are some limitations to this study. Our findings of reduced CYP3A4 activity and expression in the mouse and cell culture models of NAFLD indicate that the observed increase in MDZ levels in NAFLD are required to define the metabolic changes that occur specifically in the liver and intestine.

For ethical reasons, liver biopsies could not be obtained from the control group to confirm absence of NAFLD. In this group, we considered anthropometric and serum biochemical indices for inclusion of healthy subjects into the control group. The average age of the control group was approximately 7 years younger than that of NAFLD subjects (Table 1). In our previous study of healthy subjects, we found that MDZ oral clearance was only reduced by 3% for every 10-year increase in age (Woolsey et al., 2008). In the context of previous reports, results in mouse models of NAFLD have been heterogeneous with some demonstrating decreased (Yoshinari et al., 2006; Ghose et al., 2011; Wahlang et al., 2014) or induced (Fisher et al., 2008; Spruiell et al., 2014) expression of Cyp3a11. Similarly, rat models of hepatic steatosis are conflicting, with some reporting decreased Cyp3a expression (Leclercq et al., 1998) and others showing higher levels (Ghoneim et al., 2015).

Finally, we examined CYP3A4 activity in a cultured human hepatoma cell model of steatosis. Huh7 cells were grown for weeks at confluence in these experiments because native expression and activity of CYP3A4 under these conditions is enhanced (Sivertsson et al., 2010). In fatty acid–induced steatotic Huh7 cells, we found a trend toward lower (20% ± 6%, P = 0.10) mRNA expression levels in mice on a high-fat diet (n = 6) than in those on a normal diet (n = 6). In the context of previous reports, results in mouse models of NAFLD have been heterogeneous with some demonstrating decreased (Yoshinari et al., 2006; Ghose et al., 2011; Wahlang et al., 2014) or induced (Fisher et al., 2008; Spruiell et al., 2014) expression of Cyp3a11.

The effects of inflammation and associated cytokines on hepatic drug metabolism gene expression are a probable mechanism for reduced CYP3A4 activity in NAFLD (Abdel-Razzak et al., 1993; Muntané-Relat et al., 1995; Pascussi et al., 2000; Jover et al., 2002). Indeed, inflammatory infiltration occurs in SS and NASH together with increased hepatic expression of inflammatory cytokines (Gadd et al., 2014). Inflammatory cytokines, acting through nuclear factor
CYP3A in Nonalcoholic Fatty Liver Disease

κ-light-chain-enhancer of activated B cells, causes transrepression of the progesterone X receptor, a central transcription factor regulating CYP3A4 expression (Gu et al., 2006; Zhou et al., 2006). Moreover, the progesterone X receptor is downregulated by inflammatory cytokines (Pascucci et al., 2000) and its expression is reduced in human NASH (Bitter et al., 2014). Other mechanisms may be involved in the downregulation of CYP3A4 in NAFLD.

The clinical importance and drug development relevance of our findings of reduced CYP3A4 activity in NAFLD is potentially significant and remains to be further explored. Although CYP3A-metabolized medications such as some statins (which are commonly prescribed in patients with this condition) are safe, our finding that in vivo CYP3A metabolic activity is reduced in NAFLD leads one to ponder whether current drug dosing recommendations may need to be reevaluated in this population to ensure the best possible clinical outcomes for NAFLD patients with metaboliccomorbidities. Indeed, we recently found that plasma 4β-OHC concentrations are associated with atorvastatin plasma levels during routine clinical care (DeGorter et al., 2013). Future investigations to determine the importance of altered drug metabolism in NAFLD, together with studies to elucidate the molecular mechanisms involved, will be required to provide additional insights into therapies and management of this important cause of liver disease.
