Received January 29, 2015; accepted April 30, 2015

ABSTRACT

The hydroxylation and N-dechloroethylation of deuterated ifosfamide (d4IFO) and ifosfamide (IFO) by several human P450s have been determined and compared. d4IFO was synthesized with deuterium at the alpha and alpha’ carbons to decrease the rate of N-dechloroethylation and thereby enhance hydroxylation of the drug at the 4’ position. The purpose was to decrease the toxic and increase the efficacious metabolites of IFO. For all of the P450s tested, hydroxylation of d4IFO was improved and dechloroethylation was reduced as compared with nondeuterated IFO. Although the differences were not statistically significant, the trend favoring the 4’-hydroxylation pathway was noteworthy. CYP3A5 and CYP2C19 were the most efficient enzymes for catalyzing IFO hydroxylation. The importance of these enzymes in IFO metabolism has not been reported previously and warrants further investigation. The catalytic ability of the common polymorphisms of CYP2B6 and CYP2C9 for both reactions were tested with IFO and d4IFO. It was determined that the commonly expressed polymorphisms CYP2B6*4 and CYP2B6*6 had reduced catalytic ability for IFO compared with CYP2B6*1, whereas CYP2B6*7 and CYP2B6*9 had enhanced catalytic ability. As with the wild-type enzymes, d4IFO was more readily hydroxylated by the polymorphic variants than IFO, and d4IFO was not dechloroethylated by any of the polymorphic forms. We also assessed the use of specific inhibitors of P450 to favor hydroxylation in human liver microsomes. We were unable to separate the pathways with these experiments, suggesting that multiple P450s are responsible for catalyzing both metabolic pathways for IFO, which is not observed with the closely related drug cyclophosphamide.

Introduction

Ifosfamide (IFO), a DNA alkylating agent, is used in numerous cancer chemotherapeutic regimens. It is the structural isomer of the more commonly used antineoplastic and immunosuppressive agent cyclophosphamide (CPA) (Zhang et al., 2006). Toxicities associated with IFO treatment limit its use, even though the drug has proven more effective than CPA in a wide range of malignant diseases (Buda et al., 2003; Sorio et al., 2003; Donfrancesco et al., 2004; Pociti et al., 2004; Biagi et al., 2005; Kosmas et al., 2007). IFO-induced toxicities include moderate-to-severe nephrotoxicity, which occurs in ~30% of the patient population, and neurotoxicities, which occur in ~20% of the patient population (Loebstein et al., 1999; Klastersky, 2003; McCune et al., 2005). IFO treatment is also associated with life-threatening arrhythmias, heart failure, and severe encephalopathy (Zhang et al., 2006). Since IFO-associated toxicities are believed to be attributable to metabolites of the drug, improving our knowledge of IFO metabolism and its determinants may aid in patient treatment and expand the usefulness of IFO to a broader range of disease states and patient populations.

IFO is a prodrug activated via hydroxylation on the 4’ carbon by cytochrome P450s (P450s; Sladek, 1988). CYP2B6, CYP3A4, and CYP3A5 are the primary P450s responsible for the activation of IFO. However, CYP2C9 and CYP2C19 may also play a role in the activation (Roy et al., 1999; Huang et al., 2000). After hydroxylation, IFO undergoes a series of spontaneous events to produce the active metabolite ifosfamide mustard and equimolar amounts of acrolein (Fig. 1). In our studies, as well as others, acrolein measurement is used to analyze the activation of ifosfamide (Chang et al., 1993; Huang et al., 2000; Chen et al., 2004). In addition, IFO may be N-dechloroethylated by CYP2B6, CYP3A4, and CYP3A5 (Roy et al., 1999; Huang et al., 2000), ultimately leading to the inactivation of IFO and formation of the nephro- and neurotoxic metabolites 2-dechloroethylifosfamide or 3-dechloroethylifosfamide and equimolar amounts of chloroacetaldehyde (CAA). Figure 1 depicts the primary pathways for IFO metabolism. It is estimated that 25–60% of IFO is N-dechloroethylated in humans, whereas only 10% of CPA undergoes this reaction (Bruggemann et al., 1997; Carlson et al., 1998; Borner et al., 2000). It has been suggested that elevated circulating levels of CAA in IFO-treated patients are responsible for the development of IFO-specific nephrotoxicity (Woodland et al., 2000; Dubourg et al., 2001; Alekse et al., 2004). In vitro studies indicate that the minimum toxic concentration of CAA is 500 μM, which is well above the circulating levels of CAA in IFO-treated patients (0.5–109 μM).
Fig. 1. The major pathways for the metabolism of IFO. The therapeutic activation by favoring hydroxylation over CAA formation for IFO-induced toxicities (Woodland et al., 2000; Dubourg et al., 1996; Wrighton et al., 2000; Koch et al., 2002). Therefore, it has been suggested that CYP3A5 plays a more prominent role than other P450s in IFO-induced nephrotoxicity. Our studies have focused on characterizing the catalytic abilities of the P450s to ascertain the potential roles of specific P450s in IFO metabolism.

Several studies have suggested that CAA is primarily responsible for IFO-induced toxicities (Woodland et al., 2000; Dubourg et al., 2001; Aleska et al., 2004; McCune et al., 2005). Tissue expression of the P450s is highly variable; for instance, in the kidney CYP3A5 is highly expressed, whereas CYP3A4 is not (Haehner et al., 1996; Wrighton et al., 2000; Koch et al., 2002). Therefore, it has been suggested that CYP3A5 plays a more prominent role than other P450s in IFO-induced nephrotoxicity. Our studies have focused on characterizing the catalytic abilities of the P450s to ascertain the potential roles of specific P450s in IFO metabolism.

Materials and Methods

Materials. NADPH, catalase, IFO, L-a-dilauroyl-phosphocholine, L-a-dioleoyl-sn-glycero-3-phosphocholine, L-a-phosphatidylserine, acrolein, CAA, 3-aminophenol, and adenosine were all purchased from Sigma-Aldrich (St. Louis, MO). Pooled human liver microsomes (HLM) were purchased from BD Biosciences (San Jose, CA). d4IFO was prepared as described previously, and NMR analysis confirmed the positions of deuteration (Springer et al., 2007). All other reagents were reagent grade and purchased from commercial sources.

cDNA Expression and Purification of Human P450s, P450 Polymorphic Variants, and Rat Cytochrome P450 450 Reductase. Polymorphic variants of CYP2B6 (CYP2B6*4, CYP2B6*6, CYP2B6*9) were overexpressed in E. coli C41 (DE3) cells and purified as described previously (Zhang et al., 2001). All P450s were expressed as their N-terminally truncated forms to increase the expression yields (Jenkins et al., 1998; Scott et al., 2001). Rat cytochrome 450 reductase was expressed and purified as previously described (Hanna et al., 1998). CYP3A5 was a gift from Dr. James Halpert (UCSD), and CYP2C9*2 and CYP2C9*3 were gifts from Dr. Tim Tracy (University of Kentucky) (Domancki et al., 2001; Hustert et al., 2001; Hummel et al., 2005).

Assay for the Metabolism of IFO and d4IFO. The metabolism of IFO and d4IFO by the human P450s was carried out in a reconstituted system. The reconstituted system consisting of P450 and cytochrome P450 reductase (CPR) in a 1:2 molar ratio was incubated for 30 minutes at 20°C. Dilauroylphosphatidylcholine was not used in the reconstituted systems containing CYP2B6, CYP2C9, or CYP2C19 because it was not required for catalysis (data not shown). For the reactions catalyzed by CYP3A4 and CYP3A5, a mixture of L-a-dilauroyl-phosphocholine, L-a-dioleoyl-sn-glycero-3-phosphocholine, and L-a-phosphatidylserine (1:1:1) were included in the reconstituted system for optimal activity. For these studies, 60 μg of the lipid mixture was added to the proteins and the combination was incubated for 45 minutes at 4°C prior to use. The final reaction mixtures contained 1 mM P450, 2 μM CPR, 30 mM potassium phosphate (pH 7.4), 15 units of catalase, and 0–5.0 mM IFO or d4IFO in a total volume of 95 μL. The reaction mixtures were incubated at 37°C for 4 minutes followed by the addition of 5 μL of NADPH (final concentration of 1 mM) to initiate the reaction. After incubation at 37°C for 3 minutes, the reactions were terminated by the addition of 40 μL of ice-cold 5.5% zinc sulfate, 40 μL of ice-cold saturated barium hydroxide, and 20 μL of ice-cold 0.01 M HCl as described previously (Weber and Waxman, 1993). The samples were centrifuged for 10 minutes at 13,200 rpm and kept on ice prior to derivatization and quantification by high-performance liquid chromatography (HPLC).

IFO Metabolism by Pooled Human Liver Microsomes. Metabolism of IFO by HLM was determined as described above with the substitution of investigate IFO and d4IFO metabolism, the polymorphic variants of CYP2B6 (CYP2B6*4, CYP2B6*6, CYP2B6*9) and CYP2C9 (CYP2C9*2 and CYP2C9*3) were assessed for hydroxylation and N-dechloroethylation of IFO and d4IFO. These studies revealed differences in the catalytic rates of the polymorphic variants for both pathways and for both IFO and d4IFO. In brief, CYP2B6*4 and CYP2B6*6 exhibited decreased activation and inactivation for both drugs while CYP2B6*7 and CYP2B6*9 exhibited increased activation and inactivation compared with the wild-type enzymes. d4IFO was more readily activated by the variants than IFO without being inactivated (d4IFO inactivation was only observed with wild-type CYP2B6). The differences observed for the CYP2C9 variants were very small. These findings may relate to patient outcomes with IFO treatment since CYP2B6 is largely responsible for the inactivation of IFO in vivo (Yu and Waxman, 1996).
0.2 mg/ml of HLM for the reconstituted protein mixture. To inhibit CYP3A4, 5 μM ketoconazole was added to the reaction mixtures prior to initiating the reaction with NADPH. Likewise, to inhibit CYP2B6, 5 μM clopidogrel was added to the reaction mixtures prior to initiating the reaction.

**HPLC Analysis of IFO Metabolites.** Acrolein formation was analyzed by HPLC; specifically, 60 μl of the reaction mixture containing the acrolein product was incubated with 40 μl of the fluorescence reagent (30 mg 7-aminophenol and 30 μg hydroxylamine HCl dissolved in 5 ml 1 N HCl) for 25 minutes at 90°C to form the fluorescent product 7-hydroxyquinoline. The derivatized samples were then separated on an Agilent C18 column (Zorbax SB, 3.0 m/5 μm, Agilent Technologies, Santa Clara, CA), using a Shimadzu HPLC system. 7-Hydroxyquinoline was eluted isocratically with a flow rate of 0.5 ml/min. Elution of a fluorometrically monitored fluorescent product, 1-ethenoadenosine (Weber and Waxman, 1993). The Km and Vmax values for all of the P450s tested are summarized in Table 1.

To detect CAA, 60 μl of the reaction mixture was incubated with 10 μl of 100 mM adenosine in 0.25 N HCl and 10 mM NADPH. The derivatized sample was then resolved on an Agilent C18 column (Zorbax SB, 3.0 × 150 mm, 5 μM, Agilent Technologies) with a mobile phase of 20% methanol in water and it was eluted isocratically with a flow rate of 0.5 ml/min. 1-N-Ethenoadenosine was monitored fluorometrically at 411 nm with excitation at 270 nm. The derivatized product eluted at 12.7 minutes. Calibration curves for CAA quantification were generated by incubation of CAA standards in reaction mixtures containing no substrate or NADPH. The standard curve was linear from 0.5–150 μM CAA.

**Data Analysis.** Data were analyzed using GraphPad Prism software (GraphPad Software, Inc., San Diego, CA). The parameters for the enzyme kinetics were determined using nonlinear regression analysis, specifically Michaelis-Menten analysis in GraphPad Prism. Statistical significance was determined using an unpaired t-test in GraphPad Prism.

**Results**

**Metabolism of Ifosfamide and Deuterated Ifosfamide by Wild-Type Human Cytochrome P450s.** The ability of the wild-type P450s (CYP2B6, CYP2C9, CYP2C19, CYP3A4, and CYP3A5) to catalyze the activation of IFO and d4IFO was investigated in the purified reconstituted system. Figure 3 shows the kinetic data that were generated using CYP3A4. Similar data were obtained for most of the other human P450s; these data are not shown, but they are summarized in Table 1. Of the P450s tested, CYP2C9 had the least amount of activity for the metabolism of IFO. Kinetic values for CYP2C9-mediated IFO metabolism could not be determined. Previous reports have indicated that CYP3A4 is the most efficient P450 for the activation of IFO (Roy et al., 1999; Huang et al., 2000). However, our results suggest that CYP3A4 has relatively moderate efficiency for this reaction (Vmax/Km = 0.4 minutes⁻¹ m⁻³ M⁻¹) (Fig. 3 and Table 1). CYP3A5 exhibited the highest catalytic efficiency for the activation of IFO (Vmax/Km = 2.5 minutes⁻¹ m⁻³ M⁻¹), and the lowest Vmax value (0.1 pmol/min per picomole of P450). CYP2C19 was the next-most efficient for the activation of IFO (Vmax/Km = 0.9 minutes⁻¹ m⁻³ M⁻¹). CYP2B6 exhibited the largest Vmax (3.8 pmol/min per picomole of P450), which is 38-fold higher than that of CYP3A5. Similar kinetics were observed for d4IFO (Table 1 and Fig. 3). Most notably, the Km for activation by CYP2B6 was lower for d4IFO than IFO, resulting in a more efficient reaction. Likewise, the Km of CYP3A4 for d4IFO activation was reduced by a factor of 3, resulting in a more efficient reaction as well.

The amount of inactivation of IFO and d4IFO by the P450s was investigated in the same samples described above and evaluated for

N/A, CYP3A5 was not assessed for d4IFO metabolism.
the production of the inactive metabolite CAA (Table 1). CYP2C9 and CYP2C19 did not catalyze the inactivation of either IFO or d4IFO. CYP2B6 was approximately 4-fold more efficient at the inactivation of IFO than any of the other P450s tested, and this held true for d4IFO as well (Table 1). Interestingly, the $V_{\text{max}}$ values for the inactivation of d4IFO by CYP2B6 and CYP3A4 were reduced compared with IFO, resulting in reduced efficiency for the inactivation of d4IFO compared with IFO for these P450s.

Metabolism of Ifosfamide and Deuterated Ifosfamide by the Polymorphic Variants of CYP2B6 and CYP2C9. The polymorphic variants of CYP2B6 and CYP2C9 were examined for their ability to catalyze the activation of IFO and d4IFO. The polymorphic variants exhibited variable activation of IFO compared with the wild-type forms (Fig. 4A). CYP2B6*7 and CYP2B6*9 produced nearly 3-fold more acrolein than CYP2B6*1 at 1 mM IFO. However, the common polymorphic variants CYP2B6*4 and CYP2B6*6 produced approximately half of the acrolein that wild-type CYP2B6 produced. With regard to the activation of d4IFO, the polymorphic variants followed a trend similar to that observed for the activation of IFO but consistently produced more of the activated metabolite from d4IFO than from IFO (Table 2). For CYP2B6*1 and CYP2B6*7 this enhancement was statistically significant. The variants of CYP2C9 exhibited small variations in catalyzing IFO activation. As with the CYP2B6 variants, the activation of d4IFO by CYP2C9*2 and CYP2C9*3 followed the same pattern of variation as for IFO but with significantly higher levels of activated metabolite produced (Table 2).

The inactivation of IFO and d4IFO by these polymorphic variants was also assessed using the same samples described above. All of the polymorphic variants of CYP2B6 tested produced less of the inactivated metabolite than wild-type CYP2B6 (Fig. 4B). In fact, the pathway leading to the inactivation of d4IFO by the CYP2B6 variants was essentially abolished. CYP2C9 catalyzed the inactivation of IFO to a small extent, but its variants also failed to produce the inactive metabolites for both IFO and d4IFO (Table 2).

Metabolism of Ifosfamide by Human Liver Microsomes. IFO activation by HLM was determined at concentrations of 1.0 and 10.0 mM IFO (Fig. 5A). These concentrations of IFO were chosen to ensure metabolism by the respective P450s on the basis of $K_m$ values shown in Table 1. Acrolein production increased with the increased concentration of IFO, as expected. The inhibition of CYP3A4 by ketoconazole reduced IFO activation by approximately 85% at both IFO concentrations. Inhibition of CYP2B6 by clopidogrel inhibited the activation of IFO by 67% and 47% at 1 mM and 10 mM IFO, respectively.

IFO inactivation by HLM was also monitored. Incubation with ketoconazole resulted in a decrease of almost 90% in CAA production at both IFO concentrations (Fig. 5B). Inhibition of CYP2B6 by clopidogrel decreased the inactivation of IFO by approximately 40% at both concentrations.

Discussion

We have used the purified reconstituted system to assess the contributions to the hydroxylation and the N-dechloroethylation of IFO by CYP2B6, CYP2C9, CYP2C19, CYP3A4, CYP3A5, and several commonly occurring polymorphic variants of CYP2B6 and CYP2C9. We also investigated deuterium isotope effects on the metabolism of IFO. Michaelis-Menten kinetic values have been determined for all wild-type P450s in the reconstituted system, allowing for accurate comparisons between the efficiencies of the enzymes for the activation and inactivation of both IFO and d4IFO. This is the first time that CYP2C9, CYP2C19, and CYP3A5 have been evaluated for both reactions in this manner. Additionally, this is the first investigation of the metabolism of IFO by the polymorphic variants of CYP2B6 and CYP2C9. The $K_m$ values for the CYP2B6- and CYP3A4-mediated activation of IFO are similar to those previously reported (Table 1; Roy et al., 1999; Huang et al., 2000). In our hands, CYP2B6 yielded a larger $V_{\text{max}}$ than did CYP3A4, resulting in a higher efficiency for this reaction ($V_{\text{max}}/K_m$ for CYP2B6 = 0.8 minutes$^{-1}$mM$^{-1}$ versus 0.4 minutes$^{-1}$mM$^{-1}$ for CYP3A4). This observation is in contrast with previous studies that analyzed the activation of IFO using Supersomes, where it was found that CYP3A4 was the most efficient enzyme for this reaction (Roy et al., 1999; Huang et al., 2000). This discrepancy is likely a result of the different expression systems used in the two studies and the potential effect of b5, which was present in previous studies but not in our experiments. During preliminary optimization experiments we examined the effect of b5 by adding it to the reconstitution mixture at a range of ratios (0.5:1.0:0.25 to 0.5:1.0:2.0, P450/CPR/b5). We observed little enhancement in the activation of IFO by any of the P450s, with the exception of CYP3A4, for which absolutely no change was detected (data not shown). Therefore, b5 was not included in our optimized studies. Of the P450s tested, CYP3A5 had the highest efficiency for the activation of IFO (2.5 minutes$^{-1}$mM$^{-1}$). Furthermore, in patients the plasma concentrations of IFO are well above our

![Fig. 4.](image-url)
Mediated inactivation of IFO was not (McCune et al., 2005). We found the inactivation of IFO by CYP2B6 to be approximately 4-fold more efficient than CYP3A4 and CYP3A5. Previous work in Supersomes expressing CYP2C19 (Haehner et al., 1996; Wrighton et al., 2000; Aleksa et al., 2004) may be more relevant for tissue-specific activation of IFO (Haehner et al., 1996). Given the low Km, CYP3A5 may be important inactivation of IFO by CYP3A4 was observed. The deuterium isotope effect reported may be a viable tool to enhance the therapeutic efficacy and reduce the adverse effects of IFO. Metabolism of IFO and d4IFO by the polymorphic variants of CYP2B6 and CYP2C9

</table>

Deuteration of IFO enhanced the activation of IFO by CYP2B6 and CYP3A4. This is probably attributable to the inhibition of N-dechloroethylation caused by the presence of deuterium on the chloroethyl groups of IFO (Figs. 1 and 2). This is supported by the determined Vmax values for the inactivation of d4IFO, which were lower than the Vmax values for the inactivation of IFO for all of the P450s tested. An overall enhancement in the metabolism of IFO is best observed with CYP2B6, whose activation of d4IFO (Vmax/Km = 2 minutes⁻¹·mM⁻¹) was ∼2.5-fold more efficient than IFO (Vmax/Km = 0.8 minutes⁻¹·mM⁻¹), and the inactivation of d4IFO (Vmax/Km = 0.1 minutes⁻¹·mM⁻¹) was approximately 50% less efficient than for IFO (Vmax/Km = 0.2 minutes⁻¹·mM⁻¹). Thus, for the CYP2B6-mediated metabolism of d4IFO we observe an overall 5-fold change in the ratio of activation to inactivation that results in a significant enhancement of IFO metabolism. Similar changes were observed with CYP3A4 whose activation of d4IFO (Vmax/Km = 0.7 minutes⁻¹·mM⁻¹) was ∼2-fold more efficient than IFO (Vmax/Km = 0.4 minutes⁻¹·mM⁻¹), and the inactivation of d4IFO (Vmax/Km = 0.03 minutes⁻¹·mM⁻¹) was approximately 25% less efficient than for IFO (Vmax/Km = 0.04 minutes⁻¹·mM⁻¹). Thus, a >2-fold change in the ratio of activation to inactivation of IFO by CYP3A4 was observed. The deuterium isotope effects reported may be a viable tool to enhance the therapeutic efficacy and reduce the adverse effects of IFO. Metabolization of IFO to the inactivated and toxic metabolites dechloroethylifosfamide and chlorooxacetyldehyde was 25–60%. Utilizing d4IFO may inhibit the formation of the toxic metabolites (Bruggemann et al., 1997; Carlson et al., 1998; Borner et al., 2000). Additional studies with d4IFO to address the effect of the deuterium isotopes on the DNA alkylating properties of the phosphoramide mustard of IFO merit further investigation.
The polymorphic variants of CYP2B6 and CYP2C9 exhibit altered catalytic activities for both the activation and inactivation of IFO and d4IFO compared with the wild-type P450s. Lamba et al. (2003) identified differences between genders and ethnic groups in Caucasian or African-American females. The polymorphic variants CYP2B6*4 (K262R) and CYP2B6*6 (Q172H/K262R) had reduced activation and inactivation of IFO compared with CYP2B6*1. Other polymorphic variants, CYP2B6*7 (Q172H/K262R/R487C) and CYP2B6*9 (Q172H), produced more of the activated metabolite of IFO and less of the inactivated metabolite of IFO than did the wild-type enzyme. This is interesting in light of studies performed with the structural analog CPA, where Ariyoshi et al. (2011) demonstrated that CYP2B6*4 had reduced activation and conversely CYP2B6*6 had enhanced activation of CPA. The authors concluded that the Q172R variant is capable of reinstating the activity that was lost by the introduction of the K262R mutation. With CPA this was not the case, but the addition of a third single-nucleotide polymorphism (R487C in CYP2B6*7) did fully reverse the effects of the first polymorphisms. This is the first evidence that a third point mutation in CYP2B6 can reverse the direction of the effect and restore activity that was lost by the Q172H and K262R mutations. The polymorphic variant CYP2B6*8 was also investigated and determined to be catalytically inactive with IFO, as expected (data not shown) (Zhang et al., 2011). The polymorphic variants for CYP2C9 exhibited relatively small variations in catalytic efficiency compared with CYP2C9*1.

In following with our observations of the wild-type enzymes, the activation of d4IFO was improved and its inactivation was reduced or completely abolished compared with IFO for each of the polymorphic variants. At the time of this publication, two deuterated drugs (Auspex Pharmaceuticals’ SD-809 and Concert Pharmaceuticals’ CTP-499) were in clinical trials and moving toward FDA approval. This is encouraging and supports the development of d4IFO as a potential therapeutic, as the incorporation of deuterium does not appear to introduce any unexpected perturbations during metabolism by the wild-type P450s as well as the polymorphic variants tested.

To determine the ability to favor activation over inactivation in cell culture, we measured IFO metabolism by pooled HLMs and used several specific P450 inhibitors. The inhibition of CYP2B6 in HLMs by clopidogrel inhibited both the activation and inactivation of IFO by ~40–70%. This indicates a greater contribution of CYP2B6 to the metabolism of IFO than was previously reported by CYP2B6 inhibition using the monoclonal antibody inhibitor Mah2B6. Under those conditions, only an ~20% loss of activation and a 40% loss of inactivation were observed (Huang et al., 2000). With CYP2B6-genotyped HLMs, the inactivation observed with CYP2B6 inhibition was highly variable (30–90%) (McCune et al., 2005). The large variations in percentage inhibition between these experiments probably result from differences in the expression of P450s in the HLM samples and from the polymorphic nature of the P450s. Similar results were obtained with CYP3A4 inhibition, where we observed significant inhibition of both activation and inactivation of IFO (~90% for both reactions). Studies focusing only on the inactivation of IFO reported similar results with ketoconazole treatment, whereas others only observed ~50% loss of both activation and inactivation in pooled HLM inhibited with the CYP3A4 inhibitor troleandomycin (Huang et al., 2000; McCune et al., 2005). Typically CYP3A4 comprises 30–50% of all hepatic P450 enzymes, which may explain the ability of CYP3A4 to significantly contribute to the inactivation of IFO in HLM in spite of its lower catalytic efficiency for this reaction (Shimada et al., 1994). Thus, we were unable to easily separate the activation and inactivation pathways with our experimental setup.

In summary, we determined that the P450s CYP3A5 and CYP2C19 play significant roles in the metabolism of IFO. Furthermore, the polymorphic variants of CYP2B6 and CYP2C9 exhibited significant changes in IFO metabolism, indicating that interpatient metabolite levels may be greatly altered by the polymorphic nature of these enzymes. Our studies with d4IFO indicate that deuteration of IFO results in a significantly enhanced activation of IFO over inactivation for all of the P450s tested and their respective polymorphic variants, suggesting that deuterium labeling of IFO can induce metabolic switching and may be of significant value in improving the therapeutic index of this widely used chemotherapeutic drug.

Acknowledgments
The authors thank Dr. James Halpert (UCSD) for his contribution of purified CYP3A4, as well as Dr. Tim Tracy (University of Kentucky) for the gift of purified CYP2C9*2 and CYP2C9*3.

Authorship Contributions
Participated in research design: Calinski, Ludeman, Dolan, Zhang, Hollenberg.
Conducted experiments: Calinski.
Wrote or contributed to the writing of the manuscript: Calinski, Zhang, Hollenberg.
