Abstract: 222 words

Introduction: 499 words

Discussion: 1113 words

Abbreviations used are: 5-FU, 5-Fluorouracil; DPD, dihydropyrimidine dehydrogenase; $^{13}$C-uracil, [2-$^{13}$C]Uracil; BVU, 5-($^{trans}$-2-bromovinyl)uracil; LC-MS/MS, liquid chromatography-tandem mass spectrometer; IRMS, isotope ratio-mass spectrometry; LOQ, limit of quantification; CV, coefficient of variation; TLC,
thin layer chromatography; $C_{\text{max}}$, maximum plasma concentration; $t_{\text{max}}$, time to maximum plasma concentration; $\text{AUC}_t$, area under the plasma concentration-time curve from time 0 to $t$; $\lambda_z$, apparent terminal-phase disposition rate constant; $t_{1/2}$, elimination half-life; $\text{AUC}_\infty$, area under the plasma concentration-time curve from time 0 to infinity; $F$, bioavailability; $\text{CL/F}$, apparent total clearance; $V_z/F$, apparent volume of distribution.
Abstract:

Dihydropyrimidine dehydrogenase (DPD), the first enzyme in the sequential metabolism of pyrimidine, regulates blood concentrations of 5-fluorouracil, and is deeply involved in its toxicity. This study was designed to examine the effects of a DPD inhibitor on blood concentrations of [2-^{13}C]uracil (^{13}C-uracil) and ^{13}CO_2 concentration (\Delta^{13}C) expired in breath after oral or intravenous administration of ^{13}C-uracil to DPD-suppressed dogs prepared by pretreatment with 5-(\textit{trans}-2-bromovinyl)uracil (BVU), a DPD inhibitor. Area under the curve (AUC_t) of ^{13}C-uracil after oral administration at 20 \mu mol/kg to dogs pretreated with BVU at 2, 5, and 40 \mu mol/kg were 37-, 88- and 120-fold higher than those of the control dogs, respectively. In contrast, breath AUC_t of \Delta^{13}C were reduced to 0.88-, 0.47- and 0.13-fold the control values, respectively. On intravenous administration of ^{13}C-uracil at 20 \mu mol/kg to dogs pretreated with BVU at 0.5, 2, and 40 \mu mol/kg, blood AUC_t values of ^{13}C-uracil were 1.4-, 4.2- and 13-fold higher than those of the control group, respectively, while breath AUC_t were reduced to 1.0-, 0.83-, and 0.07-fold the respective control values. DPD activities in the liver cytosol of dogs pretreated with BVU at 0.5, 2, 5, and 40 \mu mol/kg were decreased to 0.71-, 0.12-, 0.06- and 0.04-fold those of the control dogs, respectively. These findings demonstrate that breath output (\Delta^{13}C) is a good marker of
hepatic DPD activity *in vivo*.
5-Fluorouracil (5-FU) is a metabolic antagonist of pyrimidine which was first synthesized by Duschinsky et al. (1957). 5-FU and its prodrugs (tegafur, carmofur, doxifluridine, capecitabine, etc.) are anticancer agents which are widely used in the management of several common malignancies including cancer of the colon, breast and skin. Due to the structural similarity of 5-FU to the pyrimidine base uracil, it is incorporated into the metabolic cycles in vivo through the same routes as uracil, exhibits antagonistic action against anabolic metabolism (e.g., inhibition of DNA synthesis and RNA function), and kills tumor cells (Diasio and Harris, 1989; Pinedo and Peters, 1988). In addition to tumors cells, however, host cells that rapidly incorporate precursors for nucleic acids selectively uptake 5-FU to cause cytotoxicity. As a result, unusually severe adverse drug reactions (e.g., diarrhea, stomatitis, mucositis, myelosuppression and neurotoxicity) occur.

The major metabolizing organ for 5-FU is the liver (Ho et al., 1986), which accounts for approximately 80% or more of the total systemic clearance (Woodcock et al., 1980; Heggie et al., 1987). 5-FU is first converted by dihydropyrimidine dehydrogenase (DPD) to 5-fluorodihydrouracil, then by dihydropyrimidinase to α-fluoro-β-ureidopropionic acid and finally by β-ureidopropionase to α-fluoro-β-alanine, ammonia and carbon dioxide (Fig. 1). These final metabolites are excreted in urine and breath.
Administration of 5-FU or a prodrug to patients with abnormal pyrimidine metabolism such as DPD deficiency, or concomitant use with a DPD inhibitor probably causes abnormally high blood concentrations of 5-FU, which result in serious adverse drug reactions (Lyss et al., 1993; Marrison et al., 1997). In a particularly notable example, the combined use of sorivudine (an anti-viral drug) and 5-FU resulted in a large number of deaths in 1993 in Japan (Okuda et al., 1997, 1998). The mechanism of this severe toxicity was attributed to the generation of 5-(trans-2-bromovinyl)uracil (BVU) from sorivudine by gut flora (Nakayama et al., 1997). BVU has strong DPD inhibitory activity. BVU, a structural analogue of 5-FU, has been conclusively determined to inhibit DPD via an irreversible (i.e., covalent binding) and mechanism-based inhibition (Desgranges et al., 1986; Nishiyama et al., 2000). Given this background, diagnostic methods able to predict and prevent adverse drug reactions to 5-FU in patients with pyrimidine metabolism disorders have been actively sought. Although several methods are now available, including quantification of urinary pyrimidine (Sumi et al., 1995, 1998), measurement of DPD activity in peripheral monocytes (Fleming et al., 1992; Johnson et al., 1997) and evaluation of DPD genotype (Ridge et al., 1998; Collie-Duguid et al., 2000), none are considered highly reliable.

[2-13C]Uracil (13C-uracil), whose C-2 position can be labelled with a stable isotope
$^{13}$C, is metabolized by pyrimidine-metabolizing enzymes and finally expired as $^{13}$CO$_2$ (Fig. 1). In the present study, to examine relationships among the degree of DPD deficiency and uracil concentrations in blood and breath output, we administered $^{13}$C-uracil to DPD-suppressed beagle dogs prepared by preadministration of BVU (nominated as DPD-deficient model) and measured DPD activities in the liver cytosol, $^{13}$CO$_2$ concentrations ($\Delta^{13}$C) in the breath and blood concentrations of $^{13}$C-uracil.
Materials and Methods

[2-^{13}C]Uracil and [2,4,5,6-^{13}C,1,3-^{15}N]uracil were purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA), and 5-(trans-2-bromovinyl)uracil (BVU) was purchased from Sigma-Aldrich (St. Louis, MO). [6-^{14}C]-5-Fluorouracil was obtained from Moravek Biochemical Inc. (Brea, CA). All other reagents were of analytical grade.

Study animals

Male Beagle dogs purchased from Nosan Corporation (Yokohama, Japan) were aged 7 to 16 months and weighed 9.0 to 13.2 kg at the time of administration. The animals were fasted overnight before use.

Administration of ^{13}C-uracil. ^{13}C-Uracil was administered by oral gavage to 3 dogs each at the doses of 10, 20, 40 and 80 µmol/kg. A further 6 dogs were intravenously or orally administered ^{13}C-uracil at 20 µmol/kg in a crossover design.

Blood sampling and plasma separation. Approximately 2.5 mL of blood was collected from each animal using a heparinized vacuum blood-sampling tube before dosing and at 10, 20, 30, 40, 50, 60, 90, 120, 180 and 240 min after oral administration, and before and at 2, 5, 10, 20, 30, 60, 90, 120, 180 and 240 min after intravenous administration. Immediately after collection, plasma was separated by centrifugation
at 3500 rpm at 4°C for 15 min and kept frozen at -80°C until measurement of $^{13}$C-uracil by liquid chromatography-tandem mass spectrometry (LC-MS/MS).

**Breath sampling.** Approximately 300 mL of breath was collected in a vinyl bag before and at 15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 180, 210 and 240 min after administration using a valve-equipped breath collection device which allows one-way breath inflow only. Approximately 200 mL of the collected breath was withdrawn from the bag with a syringe and dispensed into breath-collecting bags, which were kept at room temperature until the measurement of $^{13}$CO$_2$ by gas chromatograph isotope ratio-mass spectrometry (IRMS).

**Effects of DPD inhibitor on pharmacokinetics of $^{13}$C-uracil.** $^{13}$C-uracil at 20 µmol/kg was orally or intravenously administered to 3 beagle dogs each at 1 hr after oral administration of BVU at 2, 5, and 40 µmol/kg or 0.5, 2, and 5 µmol/kg, respectively. Plasma and breath were then collected at the sampling times above. In addition, at 1 hr after oral administration of BVU at 0.5, 2, 5, and 40 µmol/kg, the livers were excised and cytosol was prepared (n=3) by the method described below.

**Preparation of liver cytosol.** The animals were killed by bleeding under ketamin/xylazine anesthesia 1 hr after BVU administration, and the liver was perfused with physiological saline, removed, and homogenized in 3 volumes of 10 mM Tris-HCl.
buffer (pH 7.4) containing 1 mM EDTA and 0.5 mM dithiothreitol with a Polytron homogenizer followed by stirring. A portion (10 mL) of the homogenate was further homogenized with a Potter-Elvehjem homogenizer. The homogenate was centrifuged at 105,000 × g for 60 min at 4°C to obtain supernatant (cytosol). The cytosol was applied to a MicroSpin™ G-25 column (Amersham Pharmacia Biotech Inc., Piscataway, NJ) to remove endogenous substances. The eluate was collected as the enzyme source, rapidly frozen in liquid nitrogen and stored at -80°C until activity measurement.

**Sample Analysis**

**Determination of 13C-uracil in plasma by LC-MS/MS.** Plasma concentrations of 13C-uracil were measured by LC-MS/MS (TSQ7000, Thermo Finnigan, San Jose, CA) using isotope-labeled uracil (13C4, 15N2) as internal standard. After 0.25 mL of a saturated aqueous ammonium sulfate solution was added to 0.25 mL of plasma, 13C-uracil was extracted with 3 mL of acetonitrile followed by centrifugation at 1800 × g for 10 min. After the organic layer was evaporated to dryness and the residue was reconstituted in 200 µL of purified water, 50 µL of the resulting solution was injected into the LC-MS/MS and the analytes were separated by methanol/water (1: 99, v/v) using a Develosil RPAQUEOUS column (5 µm, 2.0 mm × 150 mm, Nomura Chemical Co., Ltd., Seto, Japan). The protonated molecular ions [M+1]^+ of the analytes and the
internal standard, formed by atmospheric pressure chemical ionization, were fragmented and the selected product ions were monitored (selected reaction monitoring) at a linear concentration range of 10-500 ng/mL. The limit of quantification (LOQ), defined as the lowest concentration determined with a coefficient of variation (CV) of <20% and accuracy within 20%, was 10 ng/mL. Precision (expressed as CV%) and accuracy (expressed as bias%) were <15% and within 15%, respectively, for all analyte concentrations except the LOQ.

**Analysis of $^{13}$CO$_2$ in breath by gas chromatograph IRMS.** Concentration of $^{13}$CO$_2$ in the breath were determined with a gas chromatograph IRMS (ABCA-G, PDZ-Europa Ltd., Cheshire, U.K.). $^{13}$CO$_2$/$^{12}$CO$_2$ ratios were expressed as the $\delta^{13}$C value (permil, ‰) relative to the Pee Dee Belemnite limestone standard, and changes in $\delta^{13}$C value as $\Delta^{13}$C (‰) were compared with the baseline.

**Assay of DPD activities in liver cytosol.** Enzyme reaction was performed according to the procedure of Etienne et al. (Etienne et al., 1995). Briefly, the reaction mixture consisting of 70 mM phosphate buffer (pH 7.5), 5 mM MgCl$_2$, 0.5 mM NADPH and 40 µM [6-$^{14}$C]-5-fluorouracil was incubated at 37°C for 10 min. The reaction was then stopped by heating at 90°C for 2 min. After 25 µL of 0.36 M KOH was added to the reaction mixture and kept at room temperature for 30 min, 25 µL of
0.36 M HClO₄ was added to neutralize the alkaline reaction mixture. After centrifugation, 5 µL of the supernatant was applied to a thin layer chromatography (TLC) plate (Silica gel 60F₂₅₄, Merck, Darmstadt, Germany) which was developed for about 5 cm with a mixture of ethanol/1M ammonium acetate (5:1, v/v). After drying, the plate was again developed for about 15 cm with diethyl ether/acetone/chloroform/water (50:50:40:1, by vol.).

Radioactivity in the [6-¹⁴C]-5-fluorouracil and radioactive products regions was analyzed with a bio-imaging analyzer system (BAS2000, Fuji Photo Film Co., Ltd., Tokyo, Japan). The reaction ratio, corrected by the degradation ratio calculated using a blank reaction, was expressed as the percentage of the reaction products to the total radioactivity.

**Pharmacokinetic Analysis**

Pharmacokinetic parameters for ¹³C-uracil and ¹³CO₂ were estimated using the non-compartmental pharmacokinetic methods of analysis (WinNonlin Standard version 3.1, Pharsight Co., Mountain View, CA). Maximum plasma concentration (Cₘₐₓ) and the time to Cₘₐₓ (tₘₐₓ) were expressed as the mean and SD of the values of the Cₘₐₓ and tₘₐₓ assigned from observed data. Area under the plasma concentration-time curve (AUCₜ) was calculated up to the last measurable point t by the linear trapezoidal method. The
apparent terminal-phase disposition rate constant ($\lambda_z$) was estimated by linear regression from the semilogarithmic curve of plasma concentration versus time using the last three or four points. Terminal elimination half-life ($t_{1/2}$) was calculated from $0.693/\lambda_z$. AUC$_\infty$ was calculated by extrapolation to infinity by dividing the last measured concentration by $\lambda_z$. Apparent total clearance (CL/F) was calculated from Dose/AUC$_\infty$, and the apparent volume of distribution (V$_z$/F) from (CL/F)/$\lambda_z$. Breath pharmacokinetic parameters, namely breath $t_{\text{max}}$, $C_{\text{max}}$, AUC$_t$ and $t_{1/2}$, were calculated by the same methods as plasma concentration.
Results

Pharmacokinetics of $^{13}$C-uracil

$^{13}$C-Uracil concentration in plasma. Pharmacokinetic parameters determined based on the plasma concentrations of $^{13}$C-uracil after oral administration of $^{13}$C-uracil at 10, 20, 40 and 80 µmol/kg and intravenous administration at 20 µmol/kg under fasted conditions are shown in Tables 1 and 2, respectively. Figs. 2A and 2B show plasma $^{13}$C-uracil concentration versus time curves after oral and intravenous administration, respectively. The dose-normalized AUC<sub>t</sub> values (AUC<sub>t</sub>/Dose) increased with the increase in the dose, showing that $^{13}$C-uracil exhibited non-linear pharmacokinetics. Absolute bioavailability determined from AUC<sub>∞</sub> after oral and intravenous administration was only 10.8% (Table 2) at 20 µmol/kg.

$^{13}$CO<sub>2</sub> concentration ($\Delta^{13}$C) in breath. The pharmacokinetic parameters of breath output were calculated from the $^{13}$CO<sub>2</sub> concentration ($\Delta^{13}$C) in breath versus time curve after oral administration of $^{13}$C-uracil at doses of 10, 20, 40 and 80 µmol/kg or intravenous administration at 20 µmol/kg under fasted conditions are shown in Tables 3 and 4, respectively. Figs. 3A and 3B show the $^{13}$CO<sub>2</sub> concentration ($\Delta^{13}$C) in breath versus time curves. Linear dose relationships were obtained for both breath AUC<sub>t</sub> and breath C<sub>max</sub> (Table 3).
Pharmacokinetics of $^{13}$C-uracil in DPD-suppressed dogs after oral administration

Pharmacokinetic parameters calculated from plasma concentrations of $^{13}$C-uracil together with the relative ratios of $C_{\text{max}}$, $AUC_{t}$, $AUC_{\infty}$ and $t_{1/2}$ after oral administration at 20 $\mu$mol/kg to DPD-suppressed dogs obtained by pretreatment with BVU at 2, 5, and 40 $\mu$mol/kg are shown in Table 5, and the plasma concentration of $^{13}$C-uracil versus time curve is shown in Fig. 4. Pharmacokinetics in the breath calculated from $^{13}$CO$_2$ concentration ($\Delta^{13}$C) in breath versus time curve together with the relative ratios of breath $C_{\text{max}}$, breath $AUC_{t}$ and breath $t_{1/2}$ are shown in Table 6, and $\Delta^{13}$C in breath versus time curve is shown in Fig. 5.

Pharmacokinetics of $^{13}$C-uracil in DPD-suppressed dogs after intravenous administration

Pharmacokinetic parameters calculated from the plasma concentrations of $^{13}$C-uracil together with the relative ratio of $AUC_{t}$, $AUC_{\infty}$ and $t_{1/2}$ after intravenous administration at 20 $\mu$mol/kg to DPD-suppressed dogs obtained by pretreatment with BVU at 0.5, 2, and 40 $\mu$mol/kg are listed in Table 7, and the plasma concentration of $^{13}$C-uracil versus time curve is shown in Fig. 6. Pharmacokinetics in the breath calculated from $^{13}$CO$_2$ concentration ($\Delta^{13}$C) in breath versus time curve together with the relative ratio of breath $C_{\text{max}}$, breath $AUC_{t}$ and breath $t_{1/2}$ are shown in Table 8, and $\Delta^{13}$C in breath versus
time curve is shown in Fig. 7.

**DPD activities in liver cytosol**

DPD activities in the untreated group and the groups pretreated with BVU at 0.5, 2, 5 and 40 µmol/kg are shown in Fig. 8. Relative ratios with respect to the untreated group were 0.71, 0.12, 0.06 and 0.04, respectively.
Discussion

As part of our studies into the prediction of adverse reactions to treatment with the anticancer agent 5-FU, we investigated the effects of inhibition of DPD on blood concentrations of $^{13}$C-uracil and breath concentrations of $^{13}$CO$_2$ ($\Delta^{13}$C) after oral or intravenous administration of $^{13}$C-uracil to dogs prepared by pretreatment with BVU, a DPD inhibitor. Results showed that the breath output ($\Delta^{13}$C) is a good marker of hepatic DPD activity in vivo.

We assumed that the DPD reaction is the rate limiting step in uracil or 5-FU elimination. Because this reaction is the first step in uracil metabolism while CO$_2$ is the end product of the final step, we reasoned that if an intermediate step became rate limiting, breath analysis would reflect that limitation. In contrast, in DPD-deficient subjects, DPD would be rate limiting for overall pyrimidine metabolism.

Results showed that the pharmacokinetic parameters (breath AUC$_t$ and breath C$_{\text{max}}$) obtained from the $^{13}$CO$_2$ concentrations ($\Delta^{13}$C) in the breath exhibited a linear relationship within the dose range of 10 to 80 $\mu$mol/kg. In contrast, pharmacokinetic parameters (C$_{\text{max}}$ and AUC$_t$) determined from $^{13}$C-uracil concentrations in plasma were non-linear. The time profile of $\Delta^{13}$C in breath after intravenous administration was closely similar to that after oral administration (Fig. 3B), and similar values were
observed with respect to those pharmacokinetic parameters (Table 4). This finding indicates that the absorption of $^{13}$C-uracil was extremely rapid and the extent of absorption was very high. This is further supported by the finding that radioactivity recoveries in the breath, urine and feces after oral [2-$^{14}$C]uracil administration at 20 $\mu$mol/kg to dogs were 90.6%, 5.6% and 0.7%, respectively, of the dose given by 168 hr (data not shown). This non-linearity in blood concentration is likely due to the saturation of first-pass metabolism in the liver. In contrast, $^{13}$C-uracil that escaped the first-pass effect and entered the systemic circulation should be finally metabolized in the liver and excreted as $^{13}$CO$_2$. In other words, breath C$_{\text{max}}$ and breath AUC$_t$ represent the maximal metabolic activity ($V_{\text{max}}$) but not its affinity ($K_m$). This would explain why $\Delta^{13}$C in the breath output remained linear regardless of dosage route, and increased with the increase in dose.

The relative ratios of C$_{\text{max}}$, AUC$_t$, AUC$_{\infty}$ and $t_{1/2}$ were significantly increased as BVU dosage increased (Table 5). Moreover, the bioavailability (F) of $^{13}$C-uracil increased from 10.8% (control) to 105% (BVU 40 $\mu$mol/kg), indicating that the saturation of DPD by BVU is stronger and complete at higher doses. The V$_z$/F value therefore decreased with the increase in BVU dose, while the V$_z$ value calculated using F ranged 0.7-0.9 L/kg (Table 5), close to the 0.7 L/kg (Table 2) obtained after intravenous administration.
Thus, it was indicated that BVU has no substantial effect on the drug distribution process. On the contrary, the relative ratios of breath $C_{\text{max}}$ and breath AUC$_t$ decreased as the BVU dose increased (Table 6), indicating that the breath output of $^{13}$CO$_2$ reflects DPD activity in vivo. The delay of $t_{\text{max}}$ (Fig. 5) may be explained by the decrease in $^{13}$CO$_2$ production due to the DPD suppression. The direct correlation between breath $C_{\text{max}}$ and liver DPD activity (Fig. 9A), and breath $C_{\text{max}}$ and plasma clearance of $^{13}$C-uracil (Fig. 9B) demonstrates that the change in breath $C_{\text{max}}$ is a sensitive indicator of a decrease in DPD activity.

The relative ratios of AUC$_t$ and $t_{1/2}$ after intravenous administration of $^{13}$C-uracil increased markedly as BVU dosage increased (Table 7), although to a lesser degree than after oral administration. The relative ratios of breath $C_{\text{max}}$ and breath AUC$_t$ remarkably decreased as BVU dosage increased (Table 8). These decreases in breath parameters were approximately the same as those after oral administration at the same BVU doses (2 and 40 $\mu$mol/kg).

The rate-limiting factor of clearance for drugs with a high first-pass effect is hepatic blood flow after intravenous administration, but hepatic intrinsic clearance after oral administration (Shand et al., 1975). The limiting factor of clearance is therefore different between intravenous and oral routes of administration. Approximately 90%
of $^{13}$C-uracil is subject to first-pass metabolism, a similar ratio to that for 5-FU (Almersjo et al., 1980; Sawai et al., 1997; Kuan et al., 1996). DPD activity is localized predominately in the liver (Ho et al., 1986). DPD activity in the liver of the group pretreated with BVU at 0.5 µmol/kg as a ratio of that of the untreated group was 0.71, or in other words decreased by approximately 30%. Thus, given that blood flow is the rate-limiting factor in intravenous administration, even though DPD activity was decreased by about 30%, the decrease had little influence on blood concentration (Fig. 6), and the change in breath reaction was small (Fig. 7). On the contrary, blood concentration after oral administration directly reflects a change in DPD activity (capacity of enzyme reaction). The differences observed in the relative blood concentration ratios between the intravenous and oral administration routes with respect to the untreated controls can therefore be explained by the difference in the susceptibility of clearance to the decrease in intrinsic clearance.

Because approximately 90% of the dose was excreted as $^{13}$CO$_2$ in breath in the DPD-normal model, it is assumed that 10% remained as parent drug in the blood. If 70% of the dose were excreted in breath in the DPD-deficient model, the remaining parent drug would be noticeably elevated three-fold above the normal model (10%→30%), whereas changes in the breath response would not be large, namely only a 20% reduction.
(90%→70%). This interpretation may explain the pharmacokinetic discrepancy seen between breath excretion ($\Delta^{13}C$) and plasma $^{13}C$-uracil concentrations following the moderate suppression (i.e., 30%) of DPD activity. On the other hand, when DPD activity was markedly decreased (i.e., to 10% of the control), the breath output of $^{13}C\text{O}_2$ was remarkable and easily detected.

The most important finding of the present study is that the breath response ($\Delta^{13}C$) reflected the degree of DPD activity in the liver (Figs. 9A and 9B). Sludden et al. (1998) showed that the species order of DPD activity was mouse > rat > human > dog ≥ cynomolgus monkey ≥ rhesus monkey, while Collins (1985) showed that the clearance values of 5-FU were similar in dogs and humans. Khor et al. (1997) stated that the pharmacokinetics of 5-FU in the DPD-deficient state in humans could be predicted from animal data, including dogs. We therefore speculate that the DPD-deficient dog model is a good surrogate model for humans. Our DPD-deficient model may be useful for the preliminary assessment of inter-individual variability in 5-FU pharmacokinetics and toxicity caused by genotype-dependent DPD deficiency in humans. Further study is required to evaluate the clinical use of $^{13}C$-uracil breath testing in the identification of DPD-deficient patients before 5-FU cancer chemotherapy.
