Abstract

Our objective was to evaluate the pharmacokinetics of metformin during pregnancy. Serial blood and urine samples were collected over one steady-state dosing interval in women treated with metformin during early- to late-pregnancy (n=35) and postpartum (n=16). Maternal and umbilical cord blood samples were obtained at delivery from 12 women. Metformin concentrations were also determined in breast milk samples obtained over one dosing interval in 6 women. Metformin renal clearance increased significantly in mid- (723 ± 243 mL/min, \( P < 0.01 \)) and late-pregnancy (625 ± 130 mL/min, \( P < 0.01 \)) compared to postpartum (477 ± 132 mL/min). These changes reflected significant increases in creatinine clearance (240 ± 70 mL/min, \( P < 0.01 \) and 207 ± 56 mL/min, \( P < 0.05 \), vs. 165 ± 44 mL/min) and in metformin net secretion clearance (480 ± 190 mL/min, \( P < 0.01 \), and 419 ± 78 mL/min, \( P < 0.01 \), vs. 313 ± 98 mL/min) in mid- and late-pregnancy vs. postpartum, respectively. Metformin concentrations at the time of delivery in umbilical cord plasma ranged between nondetectable (< 5 ng/mL) to 1263 ng/mL. The daily infant intake of metformin through breast milk was 0.13-0.28 mg, and the relative infant dose was <0.5% of the mother’s weight-adjusted dose. Our results indicate that metformin pharmacokinetics are affected by pregnancy-related changes in renal filtration and net tubular transport, and can be roughly estimated by the use of creatinine clearance. At the time of delivery, the fetus is exposed to metformin concentrations from negligible to as high as maternal concentrations. In contrast, infant exposure to metformin through the breast milk is low.
Introduction

Metformin is an effective oral hypoglycemic agent that improves insulin sensitivity (Krentz and Bailey, 2005). The introduction of metformin for the treatment of polycystic ovary syndrome (PCOS) provided evidence supporting its use in pregnant women (Lord et al., 2003). Subsequently, metformin has been used during pregnancy for the treatment of gestational as well as pre-existing diabetes mellitus (Mugglestone, 2008; Wensel, 2009). Metformin is a small, basic compound that does not bind to plasma proteins (Scheen, 1996) and is a substrate for organic cation transporters (OCTs) (Wang et al., 2002; Kimura et al., 2005; Tanihara et al., 2007; Zhou et al., 2007). At doses of 0.5 to 1 g, metformin bioavailability is 40-60% and bioavailability decreases with increasing dose (Tucker et al., 1981; Scheen, 1996). The drug is eliminated primarily by the kidneys without significant metabolism. The renal clearance of metformin in men and non-pregnant women correlates with creatinine clearance, but exceeds glomerular filtration rate, indicating active net tubular secretion (Pentikäinen et al., 1979; Tucker et al., 1981; Scheen, 1996). An important role for renal OCT2 (encoded by SLC22A2) in the pharmacokinetics (PK) of metformin has been proposed based on 30-60% change in metformin secretion clearance and renal clearance, and up to 74% change in its area under the concentration-time curve (AUC), in carriers of variant SLC22A2 alleles (Song et al., 2008; Wang et al., 2008; Chen et al., 2009). Metformin crosses the placenta readily and its umbilical cord concentrations at the time of delivery are at least half of the maternal concentrations and in some cases even exceed them (Hague et al., 2003; Vanky et al., 2005; Charles et al., 2006). When metformin is used during breastfeeding, the infant exposure is low, with estimated relative infant dose reported to be 0.11-1.08% of
Despite the increasing number of pregnant women being prescribed metformin for treatment of diabetes or PCOS, and the recognition that physiological changes that occur during pregnancy may affect metformin disposition, data on the drug’s PK during gestation are limited. A study in seven women with type 2 diabetes demonstrated that metformin AUC$_{0-4\,\text{hr}}$ decreases non-significantly by 20% in late pregnancy, compared to postpartum (Hughes et al., 2006). However, only 3 post-dose blood samples were collected and the full AUC and PK parameters were not reported. Furthermore, serum creatinine was used as the indicator of renal function during pregnancy. Charles et al. suggested that metformin pharmacokinetics do not change during pregnancy, but this conclusion was based on a population PK study with maternal blood samples from only 12 late-pregnancies (with a median of 2 blood samples/pregnancy) and comparison to historic, non-pregnant controls (Charles et al., 2006). Thus, our main objective was to characterize the PK of metformin during pregnancy. We also measured umbilical cord and breast milk metformin concentrations.
Methods

Subjects

The study was approved by the Institutional Review Boards at the University of Washington, Georgetown University, as well as the University of Texas Medical Branch in Galveston, and conducted in accordance with their guidelines. All subjects gave written informed consent. We examined the steady-state PK of oral metformin in the plasma of 35 pregnant and postpartum women who were receiving the drug for therapeutic reasons that included pre-existing diabetes, gestational diabetes, and PCOS. Women were excluded from the study if their hematocrit was less than 28%. Blood and urine samples were collected during early- (10-14 weeks gestation), mid- (22-26 weeks gestation), and late-pregnancy (34-38 weeks gestation), as well as >3 months postpartum. The sample sizes of the participants at each time point varied due to differing times of enrollment and subject availability. Nine of the subjects participated in 2 study days, 6 participated in 3 study days, and 2 participated in all 4 study days. Of the women who were studied postpartum, four participated in the early-pregnancy study, 10 participated in the mid-pregnancy study, and 10 participated in the late-pregnancy study. Umbilical cord plasma samples were obtained at delivery from 12 subjects. Six women participated in the breast milk sample collections for measurement of metformin concentrations.

Dosing regimen

Oral metformin therapy was not altered for study purposes. Dosage ranged from 500 to 3000 mg/day. Two of the subjects were treated with extended release metformin tablets. The duration of the PK sampling was based on the subject’s dosage interval, which
ranged from 8 to 24 hours. Oral metformin tablets (immediate release from Caraco Pharmaceutical Laboratories, Detroit, MI; extended release from Ivax Pharmaceuticals, Miami, FL, or Apotex, Weston, FL) were provided by the investigators for the 3 days prior to each study and pill counts were conducted in 29 of the 35 subjects. The metformin supplier information was not recorded for the 6 other subjects. Subjects were asked to complete dosing calendars for documentation of administration times. They were further instructed to avoid alcohol, grapefruit and grapefruit juice for 3 days prior to each study day and to fast starting at 5 hours prior to study drug administration until 1 hour after the metformin dose on each study day. Clear liquids were allowed during the fasting portion of the study.

**Sample collection**

On each study day during pregnancy and postpartum, serial blood samples were collected: predose, then 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, 12, and 24 hours following metformin dosing, or truncated to correspond to the subject’s dosing interval. Urine collections were performed over one dosing interval, 0-8, 0-12 or 0-24 hours following metformin administration, for evaluation of metformin renal and secretion clearances as well as creatinine clearance. Umbilical cord (arterial and venous) blood samples were collected immediately after delivery. Breast milk collections were performed at 2-3 hour intervals using the Medela Classic® double electric breast pump, over one dosing interval. Both breasts were completely emptied of milk during each collection. The subjects were not allowed to breast feed their infants during the study days. Buccal swabs were collected from each of the subjects.

**Plasma and breast milk metformin analysis.**
Plasma and breast milk samples were stored at -80° C until analysis. One hundred μL of sample was mixed with 20 μL of 10 ng/μL deuterated metformin (d₆-metformin HCl, the internal standard, a total amount of 200 ng) and 250 μL of acetronitrile. Calibration standards (50 to 5000 ng/mL) and quality control samples were prepared along with each set of samples. The samples were vortexed vigorously for 10 seconds and centrifuged at 15,000 rpm (16,831 g) for 6 minutes. The protein-free supernatant was transferred to a clean tube, and 1 μL was injected onto the high-performance liquid chromatography system with mass spectrometry (LC-MS) detection.

The LC-MS system consisted of an Agilent Technologies (Palo Alto, CA, USA) 1100 Series HPLC coupled to a Series 1100, Model G1946B Mass Spectrometer. The column was a Discovery F5, 150 mm x 4.6 mm x 3 μm (Supelco, Bellefonte, PA, USA). Composition of the isocratic mobile phase was 60% 10 mM ammonium formate (pH 4.0) and 40% acetronitrile and the flow rate was 0.50 mL/min. The column was maintained at 25° C, and the autosampler tray was maintained at 4° C. The mass spectrometer was operated in the positive electrospray selected-ion monitoring (SIM) mode for ion signals at 130 m/z for metformin and 136 m/z for d₆-metformin. The dwell time for both ions was set at 289 ms. The respective voltage for the fragmentor and the capillary was set at 1000 V and 40 V. The retention time of metformin was 7.7 min, and the run time was 9.5 min. The limit of quantification was 50 ng/mL, i.e., the lowest metformin concentration that could be measured at a signal-to-noise ratio ≥ 10, with a coefficient of variation < 10% and an accuracy of 85-115%. Metformin recovery was not estimated because no extraction was performed; other than protein removal from plasma and breast milk samples by precipitation with acetonitrile, sample preparation was minimal. The
intra-day coefficient of variation was determined based on 10 replicate samples for both low (100 ng/mL) and high (2000 ng/mL) metformin concentrations, which was 1.2% and 3.2%, respectively. The inter-day coefficient of variation was determined from successive runs over 7 days for both low and high concentrations, which was 2.9% and 7.2%, respectively. Representative LC-MS chromatograms of metformin in plasma are shown in Fig. 1.

Urine metformin analysis

Ten µL of urine sample was mixed with 990 µL 10 mM ammonium formate (pH 4.0) containing 400 ng of internal standard, followed by vortexing and centrifugation as described above for plasma samples. Calibration standards (50 to 500 µg/mL) and quality control samples were prepared along side in the same manner. One-half µL of the sample was injected onto the HPLC column. The LC-MS system and instrumentation settings were the same as described for plasma samples. The limit of quantification in urine was 200 ng/mL. The intra-day coefficients of variation for low and high concentrations were 0.8% and 1.8%, respectively. The corresponding inter-day coefficients of variation were 1.5% and 2.1%.

Genotyping methods

Buccal cell DNA was isolated using a Puregene Buccal Cell Kit (Gentra Systems, Minneapolis, MN) and SLC22A2 c.808G>T polymorphism (rs316019) was determined using validated TaqMan assays from Applied Biosystems (Foster City, CA), as previously described (Hebert et al., 2008). An internal control of sequence-verified genotype was included for each assay.
Pharmacokinetic analysis

Steady-state PK parameters were estimated using standard noncompartmental techniques, as previously described (Hebert et al., 2008). Creatinine clearance was estimated by

\[
\text{CrCL} = \frac{[(\text{urine volume})(\text{urine creatinine concentration})]/[(\text{serum creatinine concentration})(\text{duration of the collection interval})].
\]

Because metformin was orally administered, its clearance and volume of distribution could not be estimated independent of its oral bioavailability (F). Hence, the parameters are reported as apparent oral clearance (i.e., \(\text{CL/F} = \text{dose}/\text{AUC}\)), and apparent oral volume of distribution (i.e., \(\text{Vb/F} = (\text{CL/F})/k_{\text{elim}}\), respectively, where \(k_{\text{elim}}\) was the terminal elimination rate constant as estimated by log-linear regression. Metformin renal net secretion clearance was estimated by

\[
\text{clearance}_{\text{secretion}} = \text{clearance}_{\text{renal}} - f_u \times \text{creatinine clearance},
\]

in which \(f_u\) was the unbound fraction of metformin in plasma and was assumed to be 1 (Scheen, 1996). One subject who was treated with extended release metformin during mid-pregnancy, but not postpartum, was not included in the analysis of apparent oral clearance and fraction excreted unchanged in the urine. Actual body weights were used for weight adjusted parameters.

The amount of metformin excreted in the breast milk for each collection interval was summed over the dosing interval (breast milk volume x concentration for each interval).

Breast milk:plasma ratio was determined by breast milk area under the concentration-time curve (AUC) / maternal plasma AUC over one dosing interval. The percentage of maternal dose excreted in breast milk was determined by (amount of metformin excreted in the breast milk over the dosing interval / maternal dose) x 100. Infant daily exposure to metformin via breast milk was calculated by (amount of metformin excreted in the
breast milk over one dosing interval x number of maternal doses per day) / body weight of an age-matched 50th percentile infant girl. Relative infant dose was calculated by

\[
\left(\frac{\text{infant daily exposure}}{\text{maternal daily dose / maternal actual weight}}\right) \times 100.
\]

**Statistical analysis**

Mann-Whitney test was used to compare the estimated PK parameters between early-, mid- or late-pregnancy and the postpartum study days. Wilcoxon signed-rank test was used for within-subject comparisons of metformin PK parameters obtained in mid- or late-gestation to those obtained postpartum. Results are reported as mean ± standard deviation, unless otherwise indicated. \( P \) value \( \leq 0.05 \) was considered significant.
Results

A total of 37 pregnant subjects (23 White, 3 Hispanic/Latina, 1 Native American, 5 Black, 2 Asian, 1 Pacific Islander, 1 Asian/Pacific Islander and 1 Pacific Islander/White) participated in this study. The subject characteristics are described in Table 1. Of the 37 subjects, two were not included in our analysis; one withdrew before completing the sampling over one dosage interval, and the other’s dosage schedule did not allow determination of metformin PK parameters with confidence. Of the other 35 subjects, 25 were OCT2 genotype G/G, 9 were G/T, and 1 subject was T/T at the G808T locus. Umbilical cord plasma samples were collected in 12 of the women at the time of delivery. Of the subjects that were studied postpartum, 6 were breastfeeding and 3 of them were studied again 4-12 weeks post-cessation of lactation. Because the PK parameters did not appear to differ between the lactation and post-cessation of lactation study days (data not shown), we report for these subjects the means of the parameters obtained during the two study days.

Due to the high inter-subject variation in PK parameters observed in our study and in previous reports (Pentikäinen et al., 1979; Tzvetkov et al., 2009), we focused our analysis on those subjects that participated in both pregnancy and postpartum study days in order to achieve the advantage of paired statistical comparison. The estimated PK parameters of metformin in those subjects are reported in Table 2. In the mid- and late-pregnancy study days, metformin renal clearance increased on average by 49% ($P < 0.01$) and 29% ($P < 0.01$), respectively, compared to postpartum (723 ± 243 mL/min and 625 ± 130 mL/min vs. 477 ± 132 mL/min, respectively), regardless of the subject’s OCT2 genotype (Table 2, Fig. 2). The changes in renal clearance paralleled the 29% ($P < 0.01$) and 21%
(P < 0.05) increases in creatinine clearance during mid- and late-pregnancy (240 ± 70 mL/min and 207 ± 56 mL/min vs. 165 ± 44 mL/min, respectively). Metformin secretion clearance was on average 45% (P < 0.01) and 38% (P < 0.01) higher in mid- and late-pregnancy than postpartum (480 ± 190 mL/min and 419 ± 78 mL/min vs 313 ± 98 mL/min, respectively). Similar changes were seen in metformin renal clearance and secretion clearance when comparisons between early-, mid- or late-pregnancy period and postpartum period were made using group means for all subjects within a study period (n=8, 18, 14, and 16 in early-, mid-, and late-pregnancy, as well as postpartum, respectively) (data not shown).

Metformin apparent oral clearance tended to increase during pregnancy, most likely reflecting the increase in its renal component, but this change was not statistically significant. In addition, the elimination half life of metformin was slightly longer at mid-pregnancy than postpartum (4.3 ± 0.9 hours vs. 3.8 ± 1.0 hours, P < 0.05), and in late-pregnancy the fraction of the drug recovered in the urine unchanged was greater (40 ± 11% vs. 35 ± 11%, P < 0.01) than postpartum (Table 2). Metformin apparent oral volume of distribution was not significantly altered during pregnancy (Table 2).

Across all subjects and all study days, metformin renal clearance correlated with both its secretion clearance (r = 0.97, P <0.01) and creatinine clearance (r = 0.80, P <0.01) (Fig. 3). A modest correlation was also observed between metformin secretion clearance and creatinine clearance (r = 0.64, P < 0.01, data not shown). The values of these parameters did not appear to differ between subjects treated for PCOS (n = 8) and those treated for pre-pregnancy or gestational diabetes (n = 25) (data not shown). In addition, the values
for carriers of the variant SLC22A2 G808T allele were within the range obtained for subjects with the G/G genotype (Fig. 3).

Because metformin bioavailability is dose-dependent (Tucker et al., 1981), we compared the drug’s PK parameters in a subset of women who received the same dose level of metformin, 500 mg twice daily (Table 3). In these subjects, metformin renal clearance and apparent oral clearance were significantly higher ($P < 0.05$) and the AUC ($P < 0.05$) and maximum concentration ($P < 0.05$) were significantly lower during mid-pregnancy than postpartum (Table 3, Fig. 4). Metformin apparent oral volume of distribution was larger during early- and mid-pregnancy than postpartum (Table 3). Metformin oral clearance correlated better in these subjects with its secretion clearance ($r = 0.80$, $P < 0.001$) than with creatinine clearance ($r = 0.65$, $P = 0.002$) (Fig. 5).

Of the 12 subjects that provided umbilical cord plasma samples at delivery, metformin cord plasma concentrations were below the limit of quantification in three. Those subjects took their last metformin dose 10, 60 or 149 hours prior to sample collection. Mean metformin concentrations in venous cord plasma of the other 9 subjects was $400 \pm 387$ ng/mL (ranged from 68 ng/mL at 2.0 hours after a 500 mg dose to 1209 ng/mL at 9.2 hours after a 2000 mg dose). Mean arterial cord plasma concentration was $417 \pm 399$ ng/mL (ranged from 55 ng/mL to 1263 ng/mL for the same subjects, respectively). Arterial cord plasma concentrations of metformin were $103 \pm 13\%$ of venous concentrations (range 81-121%).

Metformin breast milk concentrations remained relatively unchanged over the dosing interval (Fig. 6). The breast milk:plasma AUC ratio in 6 women was $0.40 \pm 0.11$.

Because a breast milk sample was missing from one woman, and breasts were not
completely emptied of milk in another, the actual amount of metformin excreted in the breast milk over one dosing interval was determined in only 4 women, treated with 1500 mg/day (n=1) or 2000 mg/day (n=3). The amounts excreted daily were 0.13 mg, 0.15 mg, 0.21 mg, and 0.28 mg, corresponding to a relative infant dose of 0.21%, 0.14%, 0.21% and 0.43% of the mother’s weight-adjusted dose, respectively.
Discussion

Despite the increasing number of women being prescribed metformin for improving insulin sensitivity in pregnancy, the data on the drug’s PK during gestation are incomplete and partially conflicting. Our study characterizes metformin PK during pregnancy and demonstrates that the physiological changes occurring during pregnancy indeed alter metformin PK.

In non-pregnant subjects, metformin’s protein binding in plasma is negligible and the drug does not undergo significant metabolism (Scheen, 1996). Thus, pregnancy-induced changes in its PK can be primarily attributed to altered renal blood flow (which leads to secondary changes in renal glomerular filtration and tubular secretion rates) and/or up-regulation in organic cation transporter-mediated active tubular secretion. Metformin net tubular secretion is unlikely to be confounded by changes in its passive tubular reabsorption, because metformin is a strong base (pKa =11.5) (Scheen, 1996). During normal pregnancy, effective renal plasma flow increases on average 50-85%, with a corresponding 50% increase in glomerular filtration rate (Davison and Dunlop, 1980; Sturgiss et al., 1994). In line with these changes in renal function, the most significant effect of pregnancy in our subjects was on metformin renal clearance. In our paired analysis, we found 49% and 29% increases in metformin renal clearance during the mid- and late-pregnancy studies, along with corresponding 29% and 21% increases in creatinine clearance. Metformin renal clearance and the fraction excreted unchanged in the urine postpartum were similar to those previously reported in non-pregnant subjects (Pentikäinen et al., 1979; Tucker et al., 1981; Sambol et al., 1995).
Our findings also indicate 45% and 38% increases in metformin secretion clearance in mid- and late-pregnancy, respectively. Metformin renal clearance correlated better with its net tubular secretion clearance ($r = 0.97$) than with creatinine clearance ($r = 0.80$), which is not surprising given metformin’s high secretory clearance. Pregnancy has been reported to induce changes in tubular secretion of endogenous compounds such as glucose and amino acids (Davison and Dunlop, 1980). Although enhanced net tubular secretion has been reported for digoxin (Hebert et al., 2008) and amoxicillin (Andrew et al., 2007) during pregnancy, little is known about the impact of pregnancy on tubular handling of most drugs. In our subjects that were studied postpartum, the mean net tubular secretion clearance of metformin (313 mL/min) was approximately two-thirds of the mean effective renal plasma flow previously reported in non-pregnant women (482 mL/min, based on four studies in a total of 62 women) (Davison and Dunlop, 1980), i.e., metformin tubular secretion is a relatively high extraction process. Given the high body weight of our postpartum subjects and possibly higher effective renal plasma flow, we may be over-estimating the extraction ratio of metformin in our subjects (Hebert et al., 2005). Because the estimated tubular extraction ratio for metformin is moderately high, the gestational changes in the drug’s net secretory clearance can potentially be explained by enhanced renal plasma flow. Alternately, the increase in net secretory clearance could signify an upregulation in the renal tubular transport mechanism of metformin.

Metformin is a substrate for renal OCTs, including OCT1, OCT2, the multidrug and excursion (MATE) transporters (Becker et al., 2009), and the plasma membrane monoamine transporter (PMAT) (Zhou et al., 2007). In humans, OCT2 plays an important role in metformin renal clearance (Song et al., 2008; Wang et al., 2008; Chen...
et al., 2009). Several studies in vitro and in animal species suggest that Oct2 expression and activity in the kidney can be regulated by steroidal hormones (Urakami et al., 1999; Shu et al., 2001; Alnouti et al., 2006). However, little is known about OCT2 regulation in humans. Hence, altered tubular secretion clearance of metformin may be suggestive of pregnancy-induced enhancement of OCT2 expression and/or function.

Several studies have recently shown that metformin pharmacokinetics are dependent in part on OCT2 genotype/activity (Song et al., 2008; Wang et al., 2008; Chen et al., 2009). The variant 808G>T, which has a high allelic frequency in all the racial populations studied, was associated with decreased secretion clearance and renal clearance in Asian homozygous and heterozygous carriers (Wang et al., 2008). In contrast, the same variant resulted in opposite changes in European-Americans and African-Americans (Chen et al., 2009). This discrepancy may be due to a linkage disequilibrium of 808G>T and four other SNPs that are frequent in the Han Chinese population, but not in European-Americans (Chen et al., 2009). The genotype-phenotype relationships of 808G>T were not evident in our study, even postpartum. This can be attributed to the different study population, as the previous studies were performed in healthy volunteers of either Asian or non-Asian race, under very controlled experimental conditions, whereas our subjects were pregnant, not healthy, and of diverse racial backgrounds, but predominantly Caucasian.

Because the association between OCT1 genotype and metformin renal clearance is weak and the MATE1 genotype did not affect metformin renal clearance (Tzvetkov et al., 2009), we did not genotype our subjects for polymorphisms in these transporters. Nevertheless, OCT1 affects metformin distribution and has been suggested to contribute
to the drug’s limited, dose-dependent gastrointestinal absorption (Shu et al., 2008). Therefore, we cannot rule out the possibility that polymorphisms in OCTs other than OCT2 could affect metformin absorption and distribution. Furthermore, altered activity of these transporters, together with other physiological changes that occur during pregnancy, could lead to gestational-induced changes in metformin oral absorption and volume of distribution. Indeed, when we limited our analysis to a subset of patients treated with the same dosage regimen, 500 mg twice daily, metformin apparent oral clearance and apparent oral volume of distribution increased, whereas the drug’s maximal concentration and AUC decreased during pregnancy (Table 3). Interestingly, in this patient subset the fraction of metformin dose excreted in the urine was not affected by pregnancy. Given that metformin is almost entirely eliminated unchanged in the urine, this suggests that pregnancy does not alter metformin absorption.

In non-pregnant patients, plasma metformin concentrations are typically in the range of 0.5–2.0 µg/mL (Scheen, 1996), but the therapeutic concentrations for metformin have not been established. Furthermore, metformin pharmacodynamics may change during pregnancy due to enhanced insulin resistance (Hebert et al., 2009). Our findings suggest that higher metformin doses may be required in pregnant patients with insufficient glycemic control, although the impact of dosages higher than 2,500 mg/day on the fetus requires further evaluation (Glueck et al., 2004; Rowan et al., 2008; Wensel, 2009).

A previous report described metformin umbilical cord serum concentrations to be comparable to the maternal concentrations or even exceed them (n=13) (Vanky et al., 2005). Similarly, our findings indicate significant placental transfer of metformin, although recent studies suggest that metformin is a safe option for the treatment of
pregnant women. No significant increase in a composite measure of neonatal complications was found among women with gestational diabetes treated with metformin, compared with insulin (Rowan et al., 2008). A follow-up for 18 months showed no differences in the growth or motor and social development of 126 infants of mothers who took metformin at conception and throughout pregnancy, compared to control infants (Glueck et al., 2004).

The amount of metformin excreted in breast milk was 0.13-0.28 mg/day (corresponding to 0.024-0.050 mg/kg/day), less than 0.5% of the mother’s weight-adjusted dose. The data are in line with those reported in previous studies that measured the drug’s excretion in breast milk over a dosage interval (Hale et al., 2002; Gardiner et al., 2003), or estimated infant exposure based on single time point measurements, in women treated with 1000-1500 mg metformin daily (Briggs et al., 2005). Importantly, a daily dose of 2000 mg in our study did not result in greater infant exposure (absolute infant dose of 0.027, 0.036 and 0.050 mg/kg/day) than 1500 mg daily (0.024 mg/kg/day in our study and the previously described values of 0.023-0.064 mg/kg/day) (Hale et al., 2002). Although the data only represent a small number of women, they suggest a saturable mechanism of metformin transfer across mammary epithelial cells, likely through OCTs (Gardiner et al., 2008). Our data suggest that, the infant is exposed to subtherapeutic doses of metformin during nursing. Furthermore, specific timing of metformin intake by the mother relative to nursing, as recommended by the general guidelines from the American Academy of Pediatrics (1997), is not expected to affect infant exposure to metformin.
Our results suggest that metformin pharmacokinetics change during pregnancy, and that creatinine clearance can be used as a gross estimate of metformin PK in the pregnant patient. In our subject population, the effect of pregnancy on metformin PK was more pronounced than the effect of $SLC22A2$ 808G>T genotype. In agreement with previous studies, we found that metformin crosses the placenta. Infant exposure to metformin through breastfeeding is low and is not expected to result in pharmacological effects.

\(\text{NS}\) indicates no statistical significance.
The estimated pharmacokinetic parameters were compared between the mid- or late-pregnancy study days and the postpartum study day. NS = not significant. "Due to the small subject number in early-pregnancy, statistical comparisons were not performed for this study day." A subject that was treated with extended release metformin during mid-pregnancy, but not postpartum, was not included in the analysis.
