**List of abbreviations:**

BChE, human butyrylcholinesterase (EC 3.1.1.8);
BMB, bambuterol;
BTCh butyrylthiocholine;
DTNB, 5,5’-dithiobis(2-nitrobenzoic acid);
HPLC, high-performance liquid chromatography;
MONO, bambuterol monocarbamate;
TBT, terbutaline;
UPLC-MS/MS, ultra-performance liquid chromatography-tandem mass spectrometry.
ABSTRACT

This paper describes the sequential hydrolysis of bambuterol enantiomers and their monocarbamate metabolites (MONO) catalyzed by human butyrylcholinesterase (BChE) as well as the enzyme inhibition resulting from this process. Particular emphasis is given to the contribution given by MONO to the enzyme inhibition since it was not fully characterized in previous works. Bambuterol and MONO enantiomers displayed the same time- and concentration-dependent mechanism of interaction with the enzyme. The hydrolysis kinetics of both bambuterol and MONO was enantioselective and the (R)-enantiomer of each compound was hydrolyzed 4-fold faster than the respective (S)-enantiomer. Despite the enzyme inhibition rates of (R)- and (S)-MONO resulted much slower than those of their respective bambuterol enantiomers (~15-fold) both MONO enantiomers showed a significant BChE inhibition when physiologically relevant concentrations of enzyme and inhibitors were used (~50% of their respective bambuterol enantiomers). The kinetic constants obtained by testing each single compound were used to model the contribution given by MONO to the enzyme inhibition observed for bambuterol. The hydrolysis of MONO enantiomers enhanced the inhibitory power of bambuterol enantiomers of about 27.5% (R) and 12.5% (S) and extended of more than 1 hour the duration of inhibition. The data indicate that MONO contribute significantly to the inhibition of BChE occurring in humans upon administration of normal doses of bambuterol. In addition the hydrolysis of MONO resulted the rate limiting step in the conversion of bambuterol in its pharmacologically active metabolite terbutaline, therefore MONO concentrations should always be monitored during pharmacokinetic studies of bambuterol.
INTRODUCTION

Bambuterol (BMB) is a bis-dimethylcarbamate prodrug of terbutaline (TBT) classified as a long-acting β2-adrenoceptor agonists (LABA). BMB is given orally for the treatment of the symptoms of asthma, and other affections characterized by bronchospasm (Olsson et al., 1984, Petrie et al., 1993). In humans, the oral administration of BMB results in a slow production of TBT making a single daily dose of BMB sufficient to maintain therapeutic levels of TBT (Nyberg et al., 1998). BMB itself has no bronchodilating effect, but it is metabolized in vivo by plasma butyrylcholinesterase (BChE, EC 3.1.1.8) into bambuterol monocarbamate (MONO, inactive) which is further metabolized by the same enzyme into the pharmacologically active compound, TBT (Tunek and Svensson, 1988). The two-step hydrolysis is described by the second-order kinetic constants $k_{11}$ and $k_{12}$ (Fig. 1). The hydrolysis mechanism in each step consists of a first stage in which one carbamate group of BMB or MONO is transferred to the active site of the enzyme which therefore results temporarily inhibited. In a successive stage the enzyme activity is restored by water that removes the carbamyl group from the active site with a rate constant $k_3$ (O’Brien et al., 1966; Main, 1979). The inhibition of plasma BChE occurring during the hydrolysis of BMB into TBT is traditionally considered the main reason accounting for the slow production of TBT observed in vivo (Sitar, 1996). An oxidative pathway for the biotransformation of BMB into TBT, most likely driven by cytochrome P450-dependent oxidases, has been observed in rat liver microsomes (Svensson and Tunek, 1988; Lindberg et al., 1989). Some evidence suggests that this metabolism might be significant also in humans (Bang et al., 1998), although its real impact on the pharmacokinetics of BMB is still not clear and requires further investigation. The inhibition of BChE by BMB has significant effects on the pharmacokinetics of other co-administered drugs which are substrates of BChE. Well known examples of these effects include the accumulation and the prolonged duration of action of the muscle relaxant drugs.
succinylcholine (Fisher et al., 1988; Staun et al., 1990), suxamethonium (Bang et al., 1990) and mivacurium (Ostergaard et al., 2000) observed in patients under BMB medication. BMB, which contains a chiral center, is currently synthesized and administered as a racemate, but there is some evidence that the (R)-enantiomer is more potent and less toxic than its mirror image (Morley, 2002; Tan and Cheng, 2009). On this basis, (R)-BMB hydrochloride has been recently approved by the Chinese State Food and Drug Administration (SFDA) for phase I clinical trials and a preliminary pharmacokinetic study has been published (Zhou et al., 2014a). On the light of the recent indications reported by the European Medicines Agency (EMA, 2012), the Food and Drug Administration (U.S. FDA, 2012), and successive suggestions (Yu and Tweedie, 2012), metabolites that are present at 25% of the parent area under time-concentration curve (AUC) (EMA and FDA) or 100% of the parent AUC (Yu and Tweedie, 2012) should be subject of further in vitro characterization of the metabolite as a possible contributor to drug-drug interactions. This is clearly the case of BMB and MONO, since the AUC of MONO (in molar units) was found to be about 300% than the AUC of BMB in a recent pharmacokinetic study (Zhou et al., 2014b). The renewed interest over BMB and the indications of the regulatory bodies emphasized the gaps in the current knowledge of BMB pharmacokinetics, and in particular on the interaction of its primary metabolite, MONO with BChE. BMB enantiomers have been characterized for their BChE inhibitory effects and (R)-BMB resulted to inhibit the enzyme about five-fold faster than (S)-BMB in vitro (Bosak et al., 2008). The racemic mixture of MONO was found about 10-fold less potent as an inhibitor of human BChE than racemic BMB (Tunek and Svensson, 1988), but its hydrolysis kinetics has not been fully characterized. In addition, the inhibitory effect of MONO enantiomers on BChE has not yet been studied.

This paper presents the stereoselective hydrolysis kinetics of BMB and MONO enantiomers and their BChE inhibition properties. The kinetic parameters obtained where used to model
the BChE inhibition caused by BMB without the contribution of MONO and to evaluate the
effect of the enzyme inhibition on the production rate of TBT. The contribution of TBT to the
inhibition of BChE was not investigated since its role at therapeutic plasma concentrations
can be considered insignificant (Kovarik and Simeon-Rudolf, 2004).
MATERIALS AND METHODS

Chemicals

(RS)-[3-[2-(tert-butylamino)-1-hydroxyethyl]-5-(dimethylcarbamoyloxy)phenyl] N,N-dimethylcarbamate hydrochloride (racemic bambuterol hydrochloride, mol. wt. 403.9), its single enantiomers and racemic terbutaline hemisulfate (mol. wt. 274.3) were kindly supplied by Dongguan Keyphar (Dongguan, PRC). The chemical purity of all compounds exceeded 99.5% and the enantiomeric excess of the single enantiomers was ≥ 99.5%.

Butyrylcholinesterase derived from human plasma (EC 3.1.1.8), S-butyrylthiocholine iodide (BTCh), 5,5’-dithiobis(2-nitrobenzoic) acid (DTNB) and neostigmine methyl sulphate (mol. wt. 223.3) were purchased from Sigma-Aldrich (Shanghai, PRC). Salbutamol hemisulfate (mol. wt. 288.4) was obtained from the Chinese National Institute for Food and Drug Control (NIFDC). Buffer salts (Ammonium acetate, NaH₂PO₄, Na₂HPO₄, NaHCO₃, NaCl, sodium EDTA, acetic acid, sodium hydroxide, ammonium hydroxide, ethyl acetate and glycerol were of analytical grade and purchased from Sigma-Aldrich (Shanghai, PRC). Solvents and additives used for chromatography (methanol, acetonitrile, reagent alcohol, hexanes, formic acid) were HPLC grade and purchased from Fisher Scientific (Guangzhou, PRC). BChE, supplied as a lyophilized powder, was dissolved in a buffer containing sodium phosphate (10 mM, pH 7.2), NaCl (50 mM), EDTA (1 mM), glycerol (10% v/v) at a nominal concentration (according to the analysis certificate provided by the supplier) of 38.5 U of butyrylcholine/mL and stored at -80°C. All the enzyme activity data reported in this paper refer to the nominal activity provided by the supplier.
Synthesis of rac-bambuterol monocarbamate hydrochloride and its single enantiomers

General synthetic approach. Racemic bambuterol monocarbamate ((RS)-3-[2-(tert-butylamino)-1-hydroxyethyl]-5-hydroxyphenyl] N,N-dimethylcarbamate hydrochloride, MONO) and its (S)- and (R)-enantiomers were synthesized by using racemic, (S)- and (R)-bambuterol as starting materials, respectively. Five aliquots of 10 mg of bambuterol hydrochloride (rac- S- or R-, 0.124 mmol) were solubilized in aqueous NaOH (0.25 M, 0.5 mL/aliquot) and left at room temperature (~26-28°C) for 12 h. The reaction was stopped by adding aqueous acetic acid (20% v/v, 100 μL/aliquot). The fractions containing MONO (rac-S- or R-) were then isolated by solid-phase extraction (SPE).

Isolation of MONO by SPE. A C-18 solid-phase extraction (SPE) cartridge (1g bed, Autoscience, Tianjin, PRC) was sequentially washed with 10 mL water, 10 mL of methanol and equilibrated with 10 mL NH₄OH 0.2% in water (SOL 1). One aliquot of reaction mixture (600 μL) was loaded onto the cartridge and terbutaline was eluted with 10 mL of SOL 1/methanol 90:10. MONO was eluted with 10 mL of SOL 1/methanol 60:40. The first mL of eluate was collected separately and discarded. Bambuterol (BMB) was eluted with 5 mL of Buffer ammonium acetate (50 mM, pH 4.6)/methanol 10:90. The cartridge was washed with 5 mL of water/methanol 10:90 and the procedure was repeated for the other aliquots of reaction mixture. The fractions of MONO obtained by SPE were pooled and the methanol content was reduced by a vacuum concentrator; aqueous HCl (0.05 M, 5 mL) was added and the fraction was lyophilized.

Chemical characterization. The identity of MONO was confirmed by mass (Xevo TQ-S, Waters, UK) and ¹H NMR (500 MHz, Bruker) spectrometries. The high-performance liquid
chromatographic (HPLC) methods used to characterize chemical purity and enantiomeric excess (e.e.) of the synthesized compounds are described in the supplemental data file (Supplemental methods S1 and S2).

In vitro measurements of BChE activity

The activity of BChE was measured in 96-well plates by an EnSpire Multimode 2300 plate reader (Perkin Elmer, MA) using the Ellman’s spectrophotometric essay (Ellman et al., 1961). Stock solutions of substrate (BTCh) were freshly prepared in water. Stock solutions of DTNB (Ellman’s reagent) were freshly prepared in sodium phosphate buffer (100 mM, pH 7, 0.15% NaHCO₃ w/v). Stock solutions of the tested compounds (rac-BMB, (R)-BMB, (S)-BMB, rac-MONO, (R)-MONO, (S)-MONO) were prepared in water. The Ellman’s essay was used to determine the second order carbamylation rate constants and IC₅₀ at low enzyme concentrations, the carbamylation kinetics at physiologically relevant concentrations, and the decarbamylation rate constant of N,N’-dimethylcarbamyl-BChE.

Inhibition kinetics at low concentration of enzyme: determination of kᵢ and IC₅₀. Solutions of purified BChE (200 μL, 0.03 U/mL) in assay buffer (sodium phosphate buffer 100 mM, pH 8) were pre-incubated at 37°C with solutions of each inhibitor (25 μL, in water) at different concentrations. At set times the pre-incubation was stopped by adding a solution (25 μL) containing the substrate (BTCh, 2.5 mM) and DTNB (3.4 mM) in assay buffer, and the enzyme activity (νₐ) was determined by monitoring the increase of concentration of yellow product at 412 nm over 5-6 min at 37°C. A sample incubated with water in place of the inhibitor was analyzed in parallel to measure the maximum enzyme activity (ν₀) at each incubation time. A blank sample containing assay buffer in place of the enzyme was measured.
for each inhibitor concentration to account for the spontaneous conversion of the substrate into product and the values obtained were subtracted from each measured activity.

Enzyme inhibition at physiologically relevant concentrations of BChE and inhibitors. The physiologically relevant concentration of BMB and MONO was set at 40 nM to equal the highest sum of BMB, MONO and TBT concentrations measured in the plasma of healthy volunteers during a pharmacokinetic study of bambuterol (Zhou et al., 2014b). This value represents a hypothetical minimum concentration of BMB reaching the circulation (i.e. considering plasma protein binding, other metabolisms, distribution to tissues, and elimination of the three species negligible). Since the plasma protein binding of BMB is low [40-50% (Rosberg et al., 1993)] and that of TBT is even lower [20% (Ryrfeldt and Ramsay, 1984)], this factor is unlikely to modify significantly the hydrolysis kinetics of BMB. The physiologically relevant concentration of BChE was set at 6.42 U/mL. This value was chosen on the basis of the lowest activity found among the previously cited healthy volunteers (Zhou et al., 2014b). An aliquot of the stock solution of BChE was diluted 4-fold in sodium phosphate buffer (50 mM, pH 7.4), and divided in fractions of 12 μL. A solution of each inhibitor (6 μL, 120 nM) in phosphate buffer (50 mM, pH 7.4) was added to the enzyme fraction and pre-incubated at 30°C (both solutions were pre-warmed 10 min at 30°C before mixing) giving a solution of BChE 6.42 U/mL and inhibitor 40 nM. At set times the pre-incubation was stopped by diluting an aliquot of the inhibitor-enzyme mixture (2 μL) into a solution pre-warmed at 37°C (498 μL) containing the substrate (BTCh 250 μM) and DTNB (340 μM) in assay buffer (sodium phosphate buffer 100 mM, pH 8). 250 μL of this solution were quickly transferred to a well of a 96-well plate and the enzyme activity (A) was determined by monitoring the increase of concentration of yellow product at 412 nm over 3 min at 37°C. A sample pre-incubated with water in place of the inhibitor was also analyzed to
measure the maximum enzyme activity ($v_0$) at each incubation time. A blank sample containing assay buffer in place of the enzyme was measured to account for the spontaneous conversion of the substrate into product and the obtained values were subtracted from each measured activity.

**Determination of the decarbamylation rate constant of N,N-dimethylcarbamyl-BChE, $k_3$.** The decarbamylation rate constant was determined by using a concentration of inhibitor able to almost completely inhibit the enzyme activity (Perola et al., 1997). This solution was then diluted down to a concentration at which the inhibitor does not show any significant inhibition and the recovery of the activity was followed over time.

An aliquot of BChE stock solution (3 μL) was mixed with a solution of rac-BMB 400 nM (3 μL) in water and pre-incubated 30 min at room temperature (final condition: BChE 19.25 U/mL, rac-BMB 200 nM). After the pre-incubation, 5 μL of this solution were diluted 300-fold into phosphate buffer (50 mM, pH 7.4) at 37°C or 30°C. At set times an aliquot of this solution (225 μL) was added to a well of a 96-well plate containing a solution (25 μL) of substrate (BTCh, 2.5 mM) and DTNB (3.4 mM). The enzyme activity ($v_j$) was determined by monitoring the increase of concentration of yellow product at 412 nm over 3-5 min at 37°C or 30°C, respectively. A sample pre-incubated with water in place of the inhibitor was also analyzed to measure the maximum enzyme activity ($v_0$) at each incubation time. A blank sample containing assay buffer in place of the enzyme was measured to account for the spontaneous conversion of the substrate into product and the obtained values were subtracted from each measured activity. The determination of $k_3$ was performed in duplicate (30°C) or in triplicate (37°C).
BMB and MONO used as substrates: simultaneous analysis of BMB, MONO and TBT levels upon incubation of a physiologically relevant concentration of BMB and MONO enantiomers with a physiologically relevant concentration of BChE by UPLC-MS/MS

Sample preparation. Solutions of rac-BMB, rac-MONO and their single enantiomers (50 μL, 48 nM) in sodium phosphate buffer (60 mM, pH 7.4) were added to aliquots of BChE stock solution (10 μL) and incubated at 30°C (final condition: BChE 6.42 U/mL, drug 40 nM). At set times (1, 2, 4, 8, 15, 30, 60, 120 and 180 min) the hydrolysis was stopped by mixing an aliquot (5 μL) of the enzyme-inhibitor mixture with 5 μL of neostigmine methyl sulfate (60 μg/mL in water). An aliquot (8 μL) of this solution was then mixed with 120 μL of internal standard (125 pg/mL salbutamol in mobile phase B) and analyzed by UPLC-MS/MS (Xevo-TQS, Waters, Manchester, UK). Each experiment was performed in triplicate. The incubation was performed at 30°C, because the hydrolysis of BMB at 37°C (in particular rac-BMB and (R)-BMB) was too fast to be monitored by a manual sampling; moreover 30°C resulted the highest temperature at which the evaporation of water did not influence significantly the measured concentrations within the whole duration of the experiment (3 hours).

UPLC/MS/MS analysis. After the addition of the internal standard, the samples were centrifuged at 10,000 g at 4°C for 10 min. The supernatant (2 μL) was injected into the ultra-performance liquid chromatography tandem mass spectrometry (UPLC/MS/MS) system Waters Xevo-TQS (Waters, Manchester, UK). The chromatographic separation and the detection of BMB, MONO and TBT was performed by using a method validated for plasma samples (Zhou et al., 2014b). The details of the analysis are reported as supplemental data (Supplemental method S3).
Data analysis

Inhibition kinetics at low concentration of enzyme: determination of $k_I$ and IC$_{50}$. The pseudo-first order rate constant ($k_{obs}$) values were calculated by plotting the residual fractional activity obtained from each inhibitor concentration ($R_t$, eq.1) as a function of time and fitted to a one-phase exponential decay equation (eq. 2) (Feaster and Quinn, 1997).

\[ R_t = v_I / v_0 \quad (1) \]

\[ R_t = R_0 \cdot \exp(-k_{obs} \cdot t) + R_\infty \quad (2) \]

where $v_I$ is the measured activity of the enzyme treated with the inhibitor after a given time of pre-incubation, $v_0$ is the activity of the enzyme treated with water at the same given time of pre-incubation, and $R_t$, $R_0$ and $R_\infty$ represent the residual fractional activity at time $t$, 0 and $\infty$, respectively. The $k_{obs}$ values were then plotted versus the concentration of inhibitor [I]. Since the relationship was linear for all the molecules under investigation, the data were analyzed as for a simple irreversible inhibition and the second-order inhibition (carbamylation) rate constant ($k_I$) was calculated from eq. 3 (Marangoni, 2003; Gazić et al., 2006):

\[ k_{obs} = k_I \cdot [I] \quad (3) \]

The second-order carbamylation rate constants were defined as $k_{I1}$ when referring to the hydrolysis of BMB to MONO and $k_{I2}$ when referring to the hydrolysis of MONO to TBT.

The residual fractional activities obtained after 1 hour of incubation were plotted against the logarithm of inhibitor concentrations and the IC$_{50}$ values were obtained by fitting the data with a standard four-parameter logistic nonlinear regression analysis (Brooks et al., 2012).

The values of $k_{I1}$ and IC$_{50}$ measured for rac-BMB, R-BMB and S-BMB were not corrected
for the potential influence of the MONO metabolite generated during the incubation, which was considered negligible. In fact the concentration of MONO generated during the experiment is expected to be of the same order of magnitude as the concentration of enzyme (about 0.4 nM), and in that range of concentrations MONO did not show significant inhibition.

_Determination of the decarbamylation rate constants of N,N-dimethyl-BChE, k₃._ The decarbamylation rate constant (k₃) was calculated by plotting the natural logarithm of the measured inhibited fraction against time according to eq. 4 (Perola et al., 1997):

\[
\ln[1 - (v_i / v_0)] = -k_3 \cdot t
\]  

(4)

where \(v_i\) is the measured activity of the enzyme pre-incubated with the inhibitor at a given time (t) after dilution, \(v_0\) is the activity of the enzyme pre-incubated with water at the same time after dilution. The slope of the linear data regression gives \(-k_3\).

_Determination of kᵢ values from UPLC-MS/MS data combined with enzymatic inhibition data obtained at the same physiologically relevant concentration of BChE and inhibitors._ The averaged time-course concentration profiles of BMB, MONO and TBT as measured by UPLC-MS/MS upon incubation of BMB and MONO with BChE were combined to the enzymatic inhibition data obtained in the same experimental conditions and analyzed by the WEB server ENZO [http://enzo.cmm.ki.si (Bevc et al., 2011)] in order to obtain the second-order carbamylation rate constants (kᵢ). The hydrolysis model used to analyze BMB enantiomers is reported in Figure 2A: BMB is hydrolyzed in a single step (i.e. the BMB-enzyme complex is considered irreversible), yielding MONO and the inactive carbamyl-
BChE with a kinetic constant $k_{I_1}$. MONO is then hydrolyzed in a single step with a kinetic constant $k_{I_2}$ to give TBT and carbamyl-BChE. At the same time the carbamyl-enzyme originating from the hydrolysis of BMB and MONO is hydrolyzed by water to the active form with a kinetic constant $k_3$. Since the two carbamate groups of BMB are identical, both BMB and MONO generate the same carbamyl-enzyme. A similar model, which considers only the step involving MONO, was used to analyze the hydrolysis of MONO enantiomers (Fig. 2B). In the case of racemic compounds (rac-BMB and rac-MONO), the above mentioned models, considering the racemate as a single compound, were used to obtain a numerical value of $k_{I_1}$ and $k_{I_2}$; in addition more complex models were evaluated, for which the two enantiomers (at half concentration of the respective racemate) act as different compounds and compete kinetically for the hydrolysis (Fig. 2C and 2D). The concentration of BChE (necessary to obtain the $k_I$ values) was set at 80 nM as this value best fit both UPLC-MS/MS and enzymatic inhibition experimental data for all the compounds. The value of $k_3$ was fixed for all the computational analyses at the experimental value obtained at 30°C (0.006424 min$^{-1}$, Tab. 1). Residual sum of squares (RSS) values were used to evaluate the goodness of fit of the different models to the experimental MS data. The ordinary differential equations (ODEs) describing each model are reported as supplemental data (Supplemental method S4).

*Calculation of the contribution of MONO to the inhibition of BChE displayed by BMB.* In order to estimate the contribution given by MONO to the enzyme inhibition observed for BMB, the $k_I$ values obtained at 30°C and 37°C were used to calculate the theoretical BChE inhibition profiles generated by the hydrolysis of BMB enantiomers without the contribution of the MONO metabolites, according to the model reported in Fig. 2E. For rac-BMB the
model reported in figure 2D was used, with BMB in place of MONO, MONO in place of TBT and \(k_{1R}\) and \(k_{1S}\) in place of \(k_{2R}\) and \(k_{2S}\), respectively. The isoactivity point was defined as the time at which BMB enantiomers display the same enzyme inhibition and was used to evaluate the contribution of MONO to the enzyme inhibition in terms of enzyme recovery speed.

*Calculation of the effect of the inhibition of BChE by BMB on the rate of TBT production.* The \(k_I\) values obtained at 37°C were used to evaluate the effect of BChE inhibition on the production of TBT at different concentrations of R-BMB and rac-BMB, using the models reported in figure 2A and 2C, respectively.
RESULTS

Synthesis of rac-bambuterol monocarbamate hydrochloride and its single enantiomers

The products were obtained as a white powder (yield, 79%). ESI-MS (m/z): 297.6 [MH]$^+$; 241.4; 223.4. $^1$H NMR, rac-MONO (500 MHz, CD3OD) δ 6.77 (t, J = 1.8 Hz, 1H), 6.66 (t, J = 1.7 Hz, 1H), 6.49 (t, J = 2.2 Hz, 1H), 4.86 – 4.80 (m, 1H), 3.17 (dd, J = 12.5, 3.2 Hz, 1H), 3.10 (s, 3H), 3.02 (dd, J = 12.5, 9.8 Hz, 1H), 2.99 (s, 3H), 1.38 (s, 9H). Chemical purity ≥99.3% (HPLC-UV at 260 nm). Enantiomeric excess: 99.5% (R-MONO), 99.4% (S-MONO).

Inhibition kinetics at low concentration of enzyme: determination of $k_I$ and IC$_{50}$

Both BMB enantiomers showed a time- and concentration-dependent inhibition of purified BChE (Supplemental Figure 1). For both the enantiomers the relationship between concentration and $k_{obs}$ was linear (Fig.3B), and the line passed through the origin indicating that the enzyme-inhibitor Michaelis complex is virtually irreversible (i.e. all the inhibitor that binds the enzyme is hydrolyzed) (Main, 1969). The inhibition kinetics was highly enantioselective, as (R)-BMB inhibited the enzyme about 4-fold faster than (S)-BMB (Tab. 1). The measured second-order carbamylation rate constants ($k_I$) and the enantioselectivity of BMB enantiomers are in agreement with data obtained with the homozygous usual variant (UU) of BChE in plasma, measured with the same method at 25°C (Gazić et al., 2006). The relatively small difference between those data and the values reported in this work (about 2-fold) is consistent with the 12°C higher incubation temperature used in this work. As observed for BMB, MONO enantiomers inhibited the enzyme in a time- and concentration dependent manner (Fig. 3A, Supplemental Figure 1), with the same inhibition mechanism and the same enantioselectivity displayed by BMB (Fig. 3B, Tab. 1). The inhibition rate of MONO enantiomers was about 15-fold slower compared to the respective BMB enantiomers, while
the fastest MONO enantiomer, (R)-MONO, was only 4-fold slower than the slowest BMB enantiomer, (S)-BMB (Tab. 1).

All the compounds showed IC_{50} values in the nanomolar range (Tab. 1). The IC_{50} of rac-BMB, (R)-BMB and (S)-BMB were about 11-fold, 9-fold and 7-fold lower than their respective MONO counterparts. The IC_{50} values of the (R)-enantiomers of both BMB and MONO were about 3-fold lower than their respective (S)-enantiomers. The measured IC_{50} for rac-BMB and rac-MONO are in good agreement with previously reported data obtained with whole blood (2.7 nM and 50 nM for rac-BMB and rac-MONO, respectively) (Tunek and Svensson, 1988).

**Determination of the decarbamylation rate constants, k_3**

The inhibition of BChE by BMB and MONO enantiomers was completely reversible, as the enzyme was able to recover 95% of its activity in 4 hours at 37°C (Fig. 3C). The recovery speed at 30°C was about half of that at 37°C (Fig. 3C, Tab. 1). The decarbamylation rate constant (k_3) measured at 37°C (Tab. 1) is in very good agreement with the value of 0.011 min^{-1} obtained with whole blood at the same temperature (value obtained replotting data published in Tunek and Svensson, 1988 according to eq. 4).

**Enzyme inhibition a physiologically relevant concentration of BChE and inhibitors**

The increase of concentration of BChE up to a physiologically relevant range (6.42 U/mL) did not modify the inhibition pattern observed for the different inhibitors at lower concentrations of enzyme. (R)-BMB was the fastest inhibitor, followed by (S)-BMB, (R)-MONO and (S)-MONO (Fig. 6A). BMB and MONO racemates inhibited the enzyme with an intermediate kinetics within those of their respective single enantiomers (Fig. 6A, 6B). Moreover, the inhibitory power followed the same pattern observed with lower enzyme concentrations: after
1 hour of incubation (R)-BMB inhibited about 64% of the enzyme, followed by rac-BMB, 50%, (S)-BMB, 43%, (R)-MONO, 38%, rac-MONO, 28% and (S)-MONO, 15%.

**Bambuterol and bambuterol monocarbamate as substrates of BChE at physiologically relevant concentrations**

The concentration profiles of BMB, MONO and TBT obtained upon incubation of BMB and MONO enantiomers with physiologic concentrations of BChE at 30 °C are reported in Fig. 4. The profiles obtained for the racemic mixtures are shown in Fig. 5.

(R)-BMB was hydrolyzed very fast when incubated with a physiological concentration of BChE. After 1 min of incubation, ∼70% of (R)-BMB was hydrolyzed to MONO and a small amount of TBT was already present (6% of the initial (R)-BMB concentration). The highest concentration of MONO was reached after 4 min of incubation (85% of the initial (R)-BMB concentration). (R)-BMB was completely hydrolyzed within 8 min and the MONO produced from its hydrolysis was almost completely hydrolyzed (96%) to TBT in 3 hours. Half of the initial concentration of (R)-BMB was transformed to TBT (t_{1/2} TBT) in about 45 min (Fig. 4).

(S)-BMB showed a much slower reactivity compared to (R)-BMB. However, most of the drug (93%) was hydrolyzed within 30 min and the highest concentration of MONO (85% of the initial (S)-BMB concentration) was reached after 30 min. After 3 hours the hydrolysis was still incomplete and the concentration of TBT was only 57% of the initial (S)-BMB concentration (t_{1/2} TBT ~ 160 min, Fig. 4).

Initially the hydrolysis of rac-BMB was initially only slightly slower than that of (R)-BMB. About 50% of rac-BMB was already hydrolyzed to MONO within 1 min and traces of TBT were detectable. About 95% of the initial concentration of rac-BMB was hydrolyzed within 30 min. The highest concentration of MONO was reached after 8 min (72% of the initial
BMB concentration). After 3 hours of incubation about 78% of the initial rac-BMB was hydrolyzed to TBT ($t_{1/2}^{\text{TBT}} \sim 60\text{ min}$, Fig. 5).

The incubation of (R)-MONO with the enzyme resulted in a faster hydrolysis than that displayed by the (R)-MONO originating from the hydrolysis of (R)-BMB. The hydrolysis was completed in 3 hours, but 96% of the initial concentration of (R)-MONO was hydrolyzed to TBT within 2 hours ($t_{1/2}^{\text{TBT}} \sim 20\text{ min}$, Fig. 4). As observed for (R)-MONO, the hydrolysis of (S)-MONO was faster than that displayed by the (S)-MONO originating from the hydrolysis of (S)-BMB. After 3 hours about 78% of the initial concentration of (S)-MONO was hydrolyzed to TBT ($t_{1/2}^{\text{TBT}} \sim 70\text{ min}$, Fig. 4). The hydrolysis of rac-MONO proceeded with an intermediate speed within those of its single enantiomers. After 3 hours of incubation about 94% of the initial concentration was hydrolyzed to TBT ($t_{1/2}^{\text{TBT}} \sim 38\text{ min}$, Fig. 5).

**Data fitting.** In order to obtain reliable $k_I$ values the concentration profiles of BMB, MONO and TBT obtained upon incubation of BMB and MONO with a physiologically relevant concentration of BChE at 30°C were analyzed together with the inhibition profiles of BChE obtained in the same experimental conditions (Fig. 6). In fact, since a quite large range of enzyme concentrations gave a reasonable fitting of the concentration profiles (as far as they were higher than the concentration of inhibitor), the exact concentration of enzyme was required to calculate reliable $k_I$. The molar concentration of active enzyme in the purified preparation used for the experiments was not known. Anyway, only a very small range of enzyme concentrations, centered at about 80 nM, could fit both the concentration profiles and the inhibition profiles of all the tested compounds. This concentration of BChE is in good agreement with the value (79 nM) that was previously estimated in plasma (Myers, 1952) confirming that the concentration of enzyme used for the experiments was representative of physiological conditions. The second-order carbamylation rate constants ($k_I$) obtained by this
analysis are reported in Tab. 1. The computed best-fit curves of the concentration profiles are reported together with the experimental data in Figs. 4 and 5 while the computed best-fit curves for the BChE inhibition profiles are reported together with the experimental data in Fig. 6A and 6B. The analysis of the concentration profiles of BMB and MONO racemates gave a reasonable good fit when the simple models, in which racemic mixtures are considered as a single species, was used (Fig. 5, $\text{RSS}_{\text{rac-BMB}} = 3.61 \times 10^{-16}$, $\text{RSS}_{\text{rac-MONO}} = 1.05 \times 10^{-16}$) and the $k_f$ values obtained were consistent with those obtained in the inhibition experiments (Tab. 1). However the fit was definitely better when a competitive model was used (Fig. 5, $\text{RSS}_{\text{rac-BMB}} = 2.08 \times 10^{-16}$, $\text{RSS}_{\text{rac-MONO}} = 4.08 \times 10^{-17}$). Interestingly, the $k_{I2}$ values for R- and S-MONO hydrolysis calculated from rac-MONO data were very close to those obtained for the single enantiomers separately (see caption to Fig.5 and Tab. 1). On the other hand the software failed in calculating reliable $k_{I1}$ and $k_{I2}$ values for BMB and MONO enantiomers from rac-BMB data, although a very good fit to the experimental data was obtained when $k_{I1}$ and $k_{I2}$ values were fixed to those obtained for the single enantiomers (Fig. 5).

Calculation of the contribution of MONO to the enzyme inhibition showed by BMB. The $k_1$ and $k_3$ values measured at 30°C and 37°C were used to calculate the theoretical enzyme inhibition profiles of BMB with and without the contribution of MONO. The calculated inhibition profiles at 30°C and 37°C are depicted in figure 6C and 6D, respectively and the results are summarized in Table 2.

Calculation of the effect of the enzyme inhibition on the production of TBT. The calculated inhibition profiles of a physiological concentration of BChE (80 nM) caused by rac-BMB and (R)-BMB concentrations obtainable in human plasma with a therapeutic dose of bambuterol (20-120 nM) are depicted in Fig. 7A, while the corresponding formation of TBT is depicted in
Fig 7B. In the case of rac-BMB, the initial production rate of TBT increases with the concentration up to 40 nM, it remains almost constant in the range 40-80 nM and decreases temporarily at higher concentrations (Fig. 7B). (R)-BMB shows a similar behavior with a slightly faster kinetics and at 80 nM a temporary reduction of the initial production rate of TBT is already observable. At the highest concentration tested (120 nM) both rac-BMB and (R)-BMB show initially a low rate of production of TBT and after about 1 hour the rate increases to values similar to those calculated at lower concentrations (Fig. 7B). The range of concentrations for which the initial rate of production of TBT is almost constant (40-80 nM) corresponds to an inhibition of the enzyme activity in the range of about 50-80%, while a lower and higher inhibition correspond to a positive or to a temporary negative dependence of the production rate of TBT versus the concentration of BMB, respectively (Fig. 7A).
DISCUSSION

It has been known for nearly three decades that bambuterol (BMB) is a substrate of BChE, and that their interaction results in a temporary inhibition of the enzyme. In the early reports the contribution given by the monocarbamate intermediate (MONO) to the inhibition of BChE observed for BMB was not fully investigated and the effect of MONO has not been taken into account in the following studies related to BMB. The present study demonstrated that at physiologically relevant concentrations of enzyme, the MONO originating from the hydrolysis of BMB plays a significant and long lasting inhibitory effect on BChE.

The interaction of BMB and MONO enantiomers with BChE was studied from two different perspectives. First, the compounds were characterized as inhibitors of the enzyme, to obtain an indirect picture of the hydrolytic process. Then the hydrolysis model was confirmed by studying BMB and MONO as substrates of the enzyme by measuring the concentrations of reagents and products over the time. The enantioselective time- and concentration-dependent inhibition mechanism obtained when BMB enantiomers were used as inhibitors is in agreement with previously reported findings (Tunek and Svensson, 1988) and confirm the hydrolysis model (Fig. 1) previously proposed (Kovarik and Simeon-Rudolf, 2004, Gazić et al., 2006). In fact, according to this model the interaction between BMB and BChE results in a virtually irreversible complex formation and this is consistent with the linear correlation between the pseudo-first order rate constant ($k_{obs}$) and BMB concentration (Fig. 2B). In addition, the IC$_{50}$, $k_f$ and $k_3$ values obtained for BMB within this work are in good agreement with those obtained with plasma and whole blood, confirming that the purified enzyme is a reliable model to study the hydrolysis of BMB catalyzed by BChE and that their interaction is not significantly affected by other blood constituents. In this study we demonstrated that the interaction between MONO enantiomers and the enzyme follows the same mechanism.
observed for BMB enantiomers (Figs. 2A and 2B) but their hydrolysis is about 15-fold slower than their respective BMB counterparts as indicated by the $k_I$ values reported in Table 1.

As a further confirmation of the hydrolysis model (Fig. 1), when BMB and MONO enantiomers were studied as substrates of the enzyme, the experimental concentration profiles of substrates and products provided a very good fit with those computed according to the model (Fig. 4) and the computed $k_I$ values were consistent with those obtained by studying the drugs as enzyme inhibitors (Tab. 1).

Second order carbamylation rate constants ($k_I$) and IC$_{50}$ are often considered indicative of the potency of inhibitors and they are used to compare different compounds. However in the case of irreversible inhibitors their interpretation in this sense might be misleading because the concentration of enzyme used to test the potency greatly influence the final result. This issue was taken into account for BMB (Tunek and Svensson, 1988), but not for MONO. For instance the ratio between the IC$_{50}$ values of (R)-BMB and (R)-MONO is about 10 (Tab. 1) and the ratio between their $k_I$ values is about 15 (Tab. 1). However, when physiologically relevant concentrations of (R)-BMB and (R)-MONO were incubated with a physiologically relevant concentration of enzyme, (R)-BMB showed an inhibition only double as much as (R)-MONO (Fig. 6A). Therefore IC$_{50}$ ratios and $k_I$ ratios clearly overestimate the inhibitory power of BMB with respect of MONO, or more in general, they overestimate the faster inhibitor with respect to the slower. For this reason the contribution of the monocarbamate intermediate to the inhibition of the enzyme by BMB enantiomers was previously underestimated (Tunek and Svensson, 1988). To emphasize this aspect, the experimental $k_I$ values were used to calculate the theoretical BChE inhibition profiles of BMB enantiomers without the contribution of the MONO generated during their hydrolysis (Fig. 6C and 6D, Tab.2). As an example, the calculation of the contribution of (R)-BMB to the total enzyme inhibition revealed that the hydrolysis of (R)-MONO enhanced the inhibitory effect of (R)-
BMB by 25% and, at 37°C, it increased the recovery time of the enzyme of about 40% (Tab. 2). In addition, the contribution of MONO greatly enhances the effect of BMB chirality on BChE inhibition in terms of both maximum inhibition and duration of effect (Fig. 6C and 6D, Tab. 2). In other words without the contribution of the respective MONO enantiomers the maximum inhibition and the duration of inhibition of (R)-BMB and (S)-BMB are quite similar.

The analysis of the impact of BChE inhibition by rac-BMB and (R)-BMB over the initial production rate of TBT (Fig. 7) showed that the increase of production rate expected upon the increase of substrate concentration is almost perfectly balanced by the decrease of rate due to the reduction of active enzyme. This is especially noticeable in the range of BMB concentrations responsible for a maximum inhibition within 50% and 80%, which is the normal range of inhibition measured upon oral administration of rac-BMB in pharmacokinetic studies (Nyberg et al., 1998; Sitar et al., 1992; Ahlström et al., 1999). Thus the inhibition of the enzyme affects the initial production rate of TBT by keeping it constant over a relatively wide range of concentrations of administered BMB, rather than lowering it (Fig. 7). However, the calculations showed that a dose of BMB able to inhibit the enzyme up to 95% can slow down the rate of production of TBT, even though only for a very short time (less than 90 min, Fig. 7). This effect can be reasonably ascribed mainly to a reduction of the hydrolysis rate of MONO, rather than a reduction of the hydrolysis rate of BMB. In fact, due to its lower $k_1$ value, the hydrolysis rate of MONO is much more sensitive to the concentration of active enzyme than BMB.

Taken together these data demonstrate that the inhibition of BChE by MONO accounts for a significant part of the inhibition observed for BMB in physiological conditions, particularly for the (R)-enantiomer. Furthermore the hydrolysis of MONO by BChE has a larger impact on the pharmacokinetics of BMB than previously considered; therefore, the concentration...
profiles of MONO should be always monitored during pharmacokinetic studies involving BMB.

The whole hydrolytic process involving BMB and BChE is here described giving a complete picture of the hydrolysis kinetics and the concurrent enzyme inhibition. For the first time the role of MONO is elucidated, and the effect of chirality demonstrated. These findings offer a valuable support to the interpretation of pharmacokinetic data obtained in humans and will help to fully unveil the properties of the two enantiomers of BMB that underlie their different therapeutical activity and toxicity, thus facilitating a better clinical use of BMB.

C, Recovery of the activity of BChE after pre-incubation with rac-BMB followed by dilution, reflecting the decarbamylation kinetics of N,N’-dimethylcarbamyl-BChE, plotted according to equation 4 (mean ± SD, n=2-3). The slope of the linear fitting corresponds to $-k_3$. The recovery was monitored up to 70% and 95% at 30°C and 37°C, respectively.
Fig. 4. Hydrolysis of BMB and MONO enantiomers incubated with purified BChE at physiological concentrations of drugs and enzyme. The drugs were pre-incubated with the enzyme ([drug] = 40 nM, BChE = 6.4 U/mL) in phosphate buffer (60 mM, pH 7.4) at 30°C. At set times the concentration of bambuterol (BMB), mono-metabolite (MONO) and terbutaline (TBT) was measured by UPLC-MS/MS. The picture show the average of 3 different experiments (± SEM) performed for each enantiomer. The concentration profiles of each molecule were combined together with their respective enzyme inhibition data displayed in Fig. 6A to compute the second-order carbamylation rate constants ($k_I$) reported in Tab. 1. The hydrolysis models employed for BMB and MONO enantiomers are depicted in Fig. 2A and 2B, respectively. The fitted curves obtained by ENZO are shown for visual comparison with the experimental data (light blue solid line).

Fig. 5. Hydrolysis of BMB and MONO racemates incubated and analyzed as described in Fig. 4. Each plot shows the average of 3 different experiments (± SEM). The concentration profiles obtained were combined together with their respective enzyme inhibition data displayed in Fig. 6B to compute the second-order carbamylation rate constants ($k_I$) reported in Tab. 1. The best fit curves obtained using different models are displayed as solid lines: fit 1, light blue, simple model ($rac$-BMB, RSS = 3.61 x 10$^{-16}$; $rac$-MONO, RSS = 1.05 x 10$^{-16}$); fit 2, violet, competitive model ($rac$-MONO, RSS = 4.08 x 10$^{-17}$); fit 3, green, competitive model with $k_I$ values fixed to those obtained for the single enantiomers ($rac$-BMB, RSS = 2.08 x 10$^{-16}$). The $k_{I2}$ values for (R)- and (S)-MONO calculated from the application of the competitive model on $rac$-MONO data were 0.622 x 10$^6$ M$^{-1}$min$^{-1}$ and 0.142 x 10$^6$ M$^{-1}$min$^{-1}$, respectively.

concentrations. B, time-course of the inhibitory activity of rac-BMB, (R)-BMB and their monocarbamate metabolites rac-MONO and (R)-MONO on purified BChE at physiological concentrations. The drugs were pre-incubated with the enzyme ([drug] = 40 nM, BChE = 6.4 U/mL) in phosphate buffer (60 mM, pH 7.4) at 30°C. At set times an aliquot of each mixture was diluted and the residual enzymatic activity was measured. The experimental results (mean ± SEM, n=3-6) were compared with the theoretical residual activity (dashed lines) calculated by ENZO from the hydrolysis profiles obtained by UPLC-MS/MS, applying the hydrolysis models depicted in figure 2 (the theoretical curves displayed were obtained with a concentration of 80 nM BChE). The theoretical curves for rac-BMB and rac-MONO correspond to the competitive models reported in figure 2C and 2D, respectively. C and D, contribution of MONO to the inhibition of BChE displayed by BMB at 30°C and 37°C. The theoretical time-course residual activity calculated by ENZO (as in A and B) for racemic BMB and its single enantiomers (solid lines) are compared to the theoretical residual activity for the three species calculated considering only the first step of hydrolysis (from BMB to MONO, dashed lines) according to the model depicted in fig 2E for (R)-BMB and (S)-BMB and the respective competitive version for rac-BMB.

**Fig. 7.** A, theoretical time-course residual activity of purified BChE calculated by ENZO at different concentrations of (R)-BMB, (solid lines) and rac-BMB, (dashed lines), and, B, the corresponding theoretical time-course of the production of terbutaline (TBT). The theoretical curves displayed were obtained by applying the models depicted in Fig 2A for (R)-BMB and Fig. 2C for rac-BMB with a concentration of 80 nM BChE. The concentrations of (R)-BMB and rac-BMB are indicated in nM unit.
