Regional Differences in Human Intestinal Drug Metabolism

Division of Pharmaceutical Technology and Biopharmacy (R.I., M.I.I., D.O., H.A.M.M., P.O.) and Division of Pharmacokinetics, Toxicology and Targeting (M.T.M., M.H.d.J.), Department of Pharmacy, University of Groningen, Groningen, The Netherlands; Faculty of Pharmacy, Universitas Indonesia, Depok, Indonesia (R.I.); Department of Surgery, University Medical Center Groningen, Groningen, The Netherlands (H.S.H.); and Department of Clinical Medicine, Aarhus University, Aarhus, Denmark (H.A.M.M.)

ABSTRACT

The intestines are key for the absorption of nutrients and water as well as drug metabolism, and it is well known that there are clear differences in the expression profile of drug metabolism enzymes along the intestinal tract. Yet only a few studies have thoroughly investigated regional differences in human intestinal drug metabolism. In this study, we evaluated phase I and phase II metabolism in matched human ileum and colon precision-cut intestinal slices (PCIS). To this end, human PCIS were incubated for 3 hours with testosterone and 7-hydroxycoumarin (7-HC) to examine phase I and phase II metabolism, respectively. Metabolite formation was assessed by high-performance liquid chromatography analysis.

Our results demonstrated that androstenedione, 6β-hydroxytestosterone, 2β-hydroxytestosterone, and 7-HC sulfate were predominantly formed in the ileum, while 15α-hydroxytestosterone and 7-HC glucuronide were mainly produced in the colon. Moreover, we also observed sex differences in phase II metabolite formation, which appeared to be higher in men compared with women. Taken together, we demonstrated that phase I metabolism predominantly occurs in ileum PCIS, while phase II metabolism mostly takes place in colon PCIS. Moreover, we revealed that human PCIS can be used to study both regional and sex differences in intestinal metabolism.

Introduction

In addition to the absorption of nutrients and water, the intestines also fulfill an important role in drug metabolism (Doherty and Charman, 2002; Ding and Kaminsky, 2003, Wang et al., 2003). This is illustrated by the high expression level of drug metabolizing enzymes along the intestinal tract (von Richter et al., 2001; Glasier et al., 2004).

In the human body, xenobiotics are metabolized via various pathways, including phase I and phase II metabolism. Phase I reactions are oxidation, reduction, and hydrolysis processes. These chemical reactions change the biologic activity of the parent compound, rendering it less or completely inactive (Chhabra, 1979). In the intestines, the most abundant group of enzymes belongs to the cytochrome P450 subfamily 3A. Nonetheless, the expression profile of CYP enzymes differs along the intestinal tract and species differences are apparent (Martignoni et al., 2006). For instance, CYP3A13 is more common in the mouse intestine than in humans, while CYP3A4/5 is predominantly found in the human small intestine (Martignoni et al., 2006). In addition, it has been shown that the mRNA levels of CYP isoforms diminish along the intestinal tract, with the highest CYP expression in the duodenum and the lowest in the colon (de Waziers et al., 1990; Martignoni et al., 2006).

Conversely, sulfotransferase (SULTs) catalyze sulfation reactions (Wang et al., 2003). This is illustrated by the high expression level of drug metabolizing enzymes along the intestinal tract (van de Kerkhof et al., 2008). Recently, it was demonstrated that precision-cut tissue slices can be used to study intestinal drug metabolism (van de Kerkhof et al., 2008).

Until now, most in vitro studies on intestinal metabolism were conducted by using subcellular fractions like microsomes or enterocytes. By using advanced analytical methods, it has been demonstrated that the majority of drug metabolism enzymes can be detected in intestinal microsomes. Moreover, it has been shown that microsomes can be used to investigate enzymatic activity and the intestinal contribution to first-pass drug metabolism (Gröer et al., 2014; Nakamura et al., 2016; Busch et al., 2018). However, microsomes lack membrane transporters as well as low abundant enzyme systems, and the enzymatic activity in microsomes is highly dependent on the isolation method (Emoto et al., 2000a; van de Kerkhof et al., 2005; Peters et al., 2016; Drozdzik et al., 2018). Recently, it was demonstrated that precision-cut tissue slices can be used to study intestinal drug metabolism (van de Kerkhof et al., 2008).

ABBREVIATIONS: 15α-TOH, 15α-hydroxytestosterone; 2β-TOH, 2β-hydroxytestosterone; 6β-TOH, 6β-hydroxytestosterone; 7-HC, 7-hydroxycoumarin; CYP, cytochrome P450; hPCIS, human precision-cut intestinal slices; HPLC, high-performance liquid chromatography; PCIS, precision-cut intestinal slices; SULTs, sulfotransferase; TT, testosterone; UGTs, uridine 5′-diphospho-N-acetylgalactosamine glycosyltransferase.
In this ex vivo model, all the different cells that constitute an organ are maintained in their original environment, allowing for cell-cell and cell-matrix interactions (Poosti et al., 2015). In precision-cut intestinal slices (PCIS) the organization of the intestinal villi and microvilli is well conserved (Pham et al., 2015). Also, the method is highly efficient, since a large number of slices can be prepared from a small tissue sample, and the slices are relatively easy to process (van de Kerkhof et al., 2005).

Here, we studied the regional differences in intestinal metabolism by using matched human ileum and colon PCIS focusing on both phase I and phase II metabolism.

Materials and Methods

Chemical

All chemicals were obtained from Sigma (Zwijndrecht, The Netherlands) unless stated otherwise. Stock solutions of testosterone (TT) and 7-hydroxycoumarin (7-HC) were prepared in methanol and stored at −20°C.

Preparation of Intestinal Slices

Healthy human ileum and colon tissue were obtained following hemicolectomy for adenocarcinoma (see Table 1 for patient characteristics). Use of human tissue was approved by the Medical Ethical Committee of the University Medical Centre Groningen (UMCG), according to Dutch legislation and the Code of Conduct for dealing responsibly with human tissue in the context of health research (www.federa.org), refraining the need of written consent for further use of coded-anonymous human tissue. The procedures were carried out in accordance with the experimental protocols approved by the Medical Ethical Committee of the UMC.

Slicing of Precision-Cut Intestinal Slices

Preparation of intestinal slices (PCIS) was carried out according to the protocol of de Graaf et al. (2010). In short, intestinal tissue was cleansed by flushing Krebs-Henseleit buffer through the lumen and subsequently divided into 2-cm segments. Afterward, intestinal cores were prepared using 3% (w/v) agarose (Sigma-Aldrich, Steinheim, Germany) in 0.9% NaCl at 37°C and embedded in an agarose core-embedding unit. Next, PCIS were prepared using a Krumdieck tissue slicer. PCIS had a wet weight of approximately 3 mg and an estimated thickness of 300–400 μm. After being sliced, PCIS were directly transferred to Krebs-Henseleit buffer to prevent loss of viability.

Incubation of Slices

After slicing, PCIS were cultured in 12-well plates containing Williams’ Medium E + Glutamax (Gibco, New York, NY) supplemented with 14 mM Glucose (Merck, Darmstadt, Germany), 50 μg/ml gentamycin (Gibco) and 2.5 μg/ml fungizone (amphotericin B; Invitrogen, Paisly, Scotland). Slices were cultured at 37°C in an 80% O2/5% CO2 atmosphere, while horizontally shaken at 90 rpm (amplitude 2 cm). For metabolism experiments, PCIS were incubated with TT (250 μM) or 7-HC (500 μM) for 3 hours.

Viability

Viability of PCIS was assessed by measuring the adenosine triphosphate content of the slices using an ATP bioluminescence kit (Roche Diagnostics, Mannheim, Germany), as previously described (de Graaf et al., 2010). Determined ATP values (picomoles) were normalized to the total amount of protein (micrograms) estimated by the Lowry method (Bio-rad RC DC Protein Assay; Bio Rad, Veenendaal, The Netherlands). Results are shown as relative values compared with the related controls.

Metabolite Analysis

Testosterone. After incubation with testosterone (TT), PCIS and medium were collected and stored at −20°C until further use. Sample extraction and high-performance liquid chromatography (HPLC) analysis were performed as described earlier (van de Kerkhof et al., 2006).

Statistics

Statistics were performed using GraphPad Prism 6.0 via two-tailed Student’s t test and Pearson rank correlation as appropriate. A minimum of three different intestines was used for each experiment, using three to six slices from each intestine per condition. The results are expressed as mean ± S.E.M. Statistical differences in ATP levels were determined using the values relative to the control values. Differences between groups were considered to be statistically significant when P < 0.05.

Results

Viability of Ileum and Colon Slices. Our laboratory previously demonstrated that rat PCIS could be used to study intestinal metabolism in vitro. To gain more insight into human metabolism, we prepared matched ileum and colon PCIS, allowing us to study regional differences in intestinal metabolism. First, we characterized viability of the slices by determining the ATP content. As shown in Fig. 2, the ATP content of human ileum PCIS significantly increased after 3 hour of culture compared with the 0 hour control, after which the levels remained stable. Similar results were obtained with colon PCIS, indicating that intestinal slices remain viable in culture for at least 24 hours.

Assessment of Phase I Metabolism in Ileum and Colon. To study phase I metabolism, we incubated ileum and colon PCIS with TT. As shown in Fig. 3, several testosterone metabolites were formed in both ileum and colon slices, e.g., androstenedione, 6α-hydroxytestosterone (6α-TOH), 15α-hydroxytestosterone (15α-TOH), and 2β-hydroxytestosterone (2β-TOH). However, there was a clear distinction between the metabolite levels in ileum and colon (Fig. 3; n = 5). Androstenedione, formed by 17β-hydroxysteroid dehydrogenase, is the main TT metabolite that can be found in both the ileum and colon with a mean concentration of 9.55 ± 2.27 (range 3.0–15.6) and 4.34 ± 0.96 (range 2.0–9.3) pmol/μg protein, respectively. 6β-TOH was also found in all patient samples, however, the levels were approximately 4.2-folds higher in the ileum than in the colon (Fig. 3; n = 5). In addition, 2β-TOH levels also appeared to be higher in the ileum than in the colon, with a mean concentration of 0.24 ± 0.11 and 0.06 ± 0.01 pmol/μg protein, respectively, although differences were not statistically significant. Regarding 15α-TOH, no differences were observed. Overall, these results suggest that the ileum plays a bigger role in phase I metabolism as compared with the colon (Supplemental Table S1).

Fig. 2. Viability (relative value) of human ileum and colon slices (n = 7). Data are expressed as mean ± S.E.M. *P < 0.05 vs. control (0 hour).
Assessment of Phase II Metabolism in Ileum and Colon. Next, we investigated phase II metabolism by using 7-HC. As shown in Fig. 4, both glucuronidation and sulfation reactions took place in the ileum and the colon (n = 7). Although not statistically significant, the concentration of 7-HC glucuronide was 2.2-fold higher in the colon compared with the ileum. In contrast, there was no statistically significant difference in sulfation in the ileum and colon. Furthermore, Fig. 4 shows that, in the colon, 7-HC glucuronide levels were 5.8 times higher compared with 7-HC sulfate (P < 0.05). Taken together, these results suggest that phase II reactions are more prevalent in the colon than the ileum, especially regarding glucuronidation.

Furthermore, we studied the overall occurrence of phase I and II metabolism in the ileum and colon by comparing relative metabolite formation. A ratio higher than one (r > 1) indicates that the metabolites were more prevalent in the ileum than the colon. Conversely, a ratio of less than 1 (r < 1) shows that the metabolites were present mainly in the colon instead of the ileum. As shown in Fig. 5, androstenedione, 6α-TOH, 2β-TOH, and 7-HC sulfate, were predominantly found in the ileum instead of the colon. While 15α-TOH (0.69), and 7-HC glucuronide (0.45) levels were higher in the colon rather than the ileum (Supplemental Table S1).

Moreover, as illustrated in Fig. 6, we also observed sex differences in phase II metabolite formation, which appeared to be higher in men compared with women.

Influence of Viability on Metabolite Formation. To exclude the possibility that metabolite formation was influenced by the viability of the slices we performed a correlation analysis, which revealed no significant correlation between the ATP content of the slices and the formation of most phase I and phase II metabolites, both in the ileum and colon. However, we found a trend toward a negative correlation between ATP levels and 7-HC glucuronide in the ileum (P = 0.08, r = 0.7).

Correlation between Phase I and Phase II Metabolism. Finally, to understand better the relationship between phase I and phase II metabolism, we investigated the correlation between all the studied metabolites.

As demonstrated in Fig. 7, we found a strong positive correlation in the ileum between 2β-TOH and 6β-TOH, 7-HC glucuronide and 6β-TOH, 7-HC sulfate and 6β-TOH, 7-HC glucuronide and 2β-TOH, as well as 7-HC sulfate and 2β-TOH (Supplemental Table S2). There was also a strong positive correlation between 7-HC glucuronide and 15α-TOH, as well as 7-HC sulfate and 7-HC glucuronide in the colon (Supplemental Table S2). However, we did not observe a correlation...
between the metabolic activity of phase I and phase II enzymes in matched slices (Supplemental Figs. S1 and S2).

Discussion

The intestines fulfill an important role in drug metabolism, and it is known that the expression levels of the involved enzymes differ along the intestinal tract. However, studies in humans are lacking, especially with regards to intraindividual differences in regional metabolism. Here, we evaluated the differences in phase I and II metabolism using matched ileum and colon hPCIS.

Our results demonstrated that the ATP level, as a marker of viability, increased after 3 hours of culture and remained elevated for 24 hours in both human ileum and colon PCIS. A similar observation was previously made using rat PCIS (van de Kerkhof et al., 2007). In addition, we found no correlation between ATP levels and the formation of phase I and phase II metabolites, in both ileum and colon (Supplemental Figs. S3 and S4). This result emphasizes that the viability of PCIS had no impact on the metabolic activity of phase I and phase II enzymes.
A unique aspect of this study was the fact that we were able to use matched ileum and colon hPCIS. This allowed us to show that there is no correlation between the metabolic rate of phase I and phase II enzymes in matched slices (Supplemental Figs. S1 and S2). This strongly suggests that the regional drug metabolism capacity is differentially regulated within one human being. Furthermore, pharmacokinetics and bioavailability of drugs are greatly affected in patients with a short small bowel following gastrointestinal surgery, and the changes will vastly differ between patients (Severijnen et al., 2004; Titus et al., 2013). Studies with matched hPCIS can aid in the identification of suitable therapies for this patient population.

We demonstrated that testosterone metabolism mostly occurred in the ileum. This result is in line with a previous study showing that protein levels of CYP3A, which exhibits testosterone 6β-hydroxylase activity (Emoto et al., 2000b), is highest in the proximal region of the intestine and declines in the distal part (McKinnon et al., 1995; Faine et al., 1997; Xie et al., 2016; Drozdzik et al., 2018). In addition, other studies revealed that CYP3A and CYP2C are the major intestinal CYPs, accounting for approximately 80% and 18%, respectively, of all CYPs (Thelen and Dressman, 2009; Nakamura et al., 2016). In line with our findings, Thelen and Dressman (2009) also showed that CYP3A content is generally higher in the proximal region of the intestine.

Our results further demonstrated that metabolism of 7-HC mostly took place in the colon. These findings corroborate previous works showing that UGTs are primarily found in the colon (Pacifici et al., 1989; Zhang et al., 2018). In contrast, Drozdzik et al. (2018) reported that UGT1A1 was the most abundant UGT in jejunum compared with other intestinal segments. However, they only measured mRNA level and protein content, not enzyme activity.

Previously, the metabolic activity in intestinal slices and intestinal rat microsomes has been compared. The results showed that the metabolic rates in intestinal slices were significantly higher for all substrates studied (including TT, 3- to 29-fold) compared with the microsomes (Martignoni et al., 2006). In addition, in agreement with our findings, Ho et al. (2017) described that CYP3A4 (as a substrate) was the most active enzyme in cryopreserved enterocytes from human small intestine followed by UGT and SULT (7-HC as a substrate), respectively.

Furthermore, we also discovered a strong correlation between several products formed by CYP3A (e.g., 8β-THO and 6β-THO; Emoto et al., 2000b; Vimmercati et al., 2017), CYP2A (15α-THO; Honkakoski and Negishi, 1997), UGT1A (7-HC glucuronide; Wang et al., 2006), and SULT1 (7-HC sulfate, Wang et al., 2006) in both the ileum and colon. These results suggest that there might be a shared regulatory mechanism between phase I and phase II enzymes. Indeed, work by Xie and colleagues demonstrated that the constitutive androstane receptor and progesterin X receptor are involved in the regulation of CYP3A and CYP2B (Xie et al., 2000), as well as specific UGT1A isoforms (Xie et al., 2003). In addition, Maglich et al. (2003) showed that constitutive androstane receptor regulates CYP2A6 and SULT1. Thus, it is clear that several signaling pathways can regulate both phase I and phase II enzymes.

We also observed that the rate of phase II metabolism was higher in male PSIC compared with female PSIC. To the best of our knowledge, sex differences in human intestinal metabolism have not been reported before. However, using human liver microsomes, Court et al. (2001) previously established that acetaminophen metabolism, catalyzed by UGT1A1, UGT1A6, and UGT1A9, was higher in men compared with women. Men also show a higher rate of clearance of several benzodiazipines (e.g., diazepam, chloridiazepoxide, and olandapine), which is catalyzed by CYP1A2. Furthermore, men more rapidly clear chloroxazone, a CYP2E1 substrate (Waxman and Holloway, 2009). Also, it is clear that endogenous sex hormones can impact hepatic enzyme activity, resulting in sex differences in pharmacokinetics (Waxman and Holloway, 2009). However, Miyauchi et al. (2016) reported that there was no significant difference between men and women in the expression level of CYPs and UGTs in human jejunal tissues. In addition, Her et al. (1996) described a large variation in the jejunal expression of SULT1E1 and SULT2A1 independent of sex or age. Thus more research is needed to characterize fully sex-based differences in intestinal drug metabolism.

In conclusion, PSIC is a promising model to investigate intestinal drug metabolism. Based on this study, it can be concluded that there is a significant difference in the rate of phase I and II metabolism in the ileum and the colon. We demonstrated that phase I metabolism predominantly occurs in ileum PSIC, while phase II metabolism mostly takes place in colon PSIC. Moreover, our study revealed that PSIC could be used to investigate sex differences in drug metabolism.
