ABSTRACT

Domoic acid (DA), a neurotoxin, is produced by marine algae and has caused toxications worldwide in animals and humans. However, the toxicokinetics of DA have not been fully evaluated, and information is missing on the disposition of DA following oral exposures at doses that are considered safe for human consumption. In this study, toxicokinetics of DA were investigated in cynomolgus monkeys following single doses of 5 μ g/kg DA intravenously, 0.075 mg/kg DA orally, and 0.15 mg/kg DA orally. After intravenous dosing, DA had a systemic clearance of 124 ± 71 (ml/h)/kg, volume of distribution at steady state of 131 ± 71 ml/kg and elimination half-life of 1.2 ± 1.1 hours. However, following oral dosing, the average terminal half-life of DA was 11.3 ± 2.4 hours, indicating that DA disposition follows flip-flop kinetics

with slow, rate-limiting absorption. The absorption of DA was low after oral dosing with absolute bioavailability of $6\% \pm 4\%$. The renal clearance of DA was variable [$21\text{--}152$ (ml/h)/kg] with $42\% \pm 11\%$ of the intravenous DA dose recovered in urine. A physiologically based pharmacokinetic model was developed for DA in monkeys and humans that replicated the flip-flop kinetics observed after oral administration and allowed simulation of urinary excretion and brain and kidney distribution of DA following intravenous and oral dosing. This study is the first to characterize DA disposition at exposure levels close to the current estimated tolerable daily intake and to mechanistically model DA disposition in a model species, providing important information of the toxicokinetics of DA for human safety assessment.

Introduction

Domoic acid (DA, Fig. 1) is a neurotoxic kainic acid and glutamate analog that binds to α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) and kainate receptors, resulting in lesions in the hippocampus and amygdala (Pulido, 2008). DA is produced by several *Pseudo-nitzschia* algal species in seawater (Mos, 2001). As *Pseudo-nitzschia* blooms are initiated by anomalously warm ocean conditions, increasing sea temperatures are predicted to increase algal blooms and consequently DA outbreaks and exposure. Indeed, in 2015, warm ocean conditions resulted in *Pseudo-nitzschia* blooms that led to the largest outbreak of DA along the North American west coast (McCabe et al., 2016). As DA is transferred through marine food webs via ingestion of *Pseudo-nitzschia* cells and by consumption of the organisms contaminated with DA (Lefebvre et al., 2002; Lefebvre and Robertson, 2010), DA intoxications in marine animals are closely tied to severity of DA-producing algal blooms (Scholin et al., 2000; Lewitus et al., 2012;

Du et al., 2016). Hence, the increase in DA outbreaks also precipitates a potential increase in public health risks of exposure to DA.

Human DA poisoning affected over 100 individuals in 1987. Three individuals died and others reported signs of DA-related amnesic shellfish poisoning, including gastrointestinal distress, neurologic abnormalities, seizures, and autonomic nervous system dysfunction (Perl et al., 1990; Todd, 1993). Analysis of nine of these cases suggested the toxication was due to consumption of DA-containing mussels at intake levels of 60–290 mg (0.9–4.1 mg/kg) of DA (Perl et al., 1990), but DA concentrations in the affected individuals could not be measured. The acute toxicity of DA has since been extensively studied, and oral acute reference doses and tolerable daily intake (TDI) values of 0.018–0.1 mg/kg have been proposed (Costa et al., 2010). A TDI of 0.075 mg/kg orally was suggested based on the no observed adverse effect level (NOAEL) in monkeys following short-term exposure (0.75 (mg/kg)/day DA orally for 15 days) (Mariën, 1996; Truelove et al., 1997). However, information to establish a chronic TDI for DA is currently not available (Pulido, 2008). Several studies in model species have suggested that chronic low-level DA exposure at asymptomatic doses results in adverse effects, including epigenetic changes and sensitization of animals to the toxicity of DA (Hiolski et al., 2014; Lefebvre et al., 2017). Yet, the underlying mechanisms of these changes and DA toxicokinetics at asymptomatic doses have not been

characterized. The lack of knowledge of the toxicokinetics of DA is largely due to limited bioanalytical methods to measure DA. LC-MS/MS methods exist for measuring DA in seawater and in contaminated seafood (Wang et al., 2012; Barbaro et al., 2016), but these methods lack the sensitivity needed to quantify DA in biological samples after low level exposure (Frame and Lefebvre, 2013). ELISA can measure DA at concentrations down to 0.4 ng/ml in biologic specimens (Frame and Lefebvre, 2013), but the ELISA also crossreacts with antibodies against DA, decreasing the usefulness of this assay following chronic exposures (Lefebvre et al., 2012). Therefore, improved LC-MS/MS methods are needed to allow evaluation of DA exposures.

DA is a polar compound ($\log P = -0.23$) with four ionized groups, three carboxylic acids (pK_a values 1.85–4.75) and an amine (pK_a 10.6) (Walter et al., 1992). Hence, it is expected to have limited permeability across physiological barriers such as intestinal epithelium, blood-brain barrier, and the placenta. Low permeability of DA in Caco-2 cells has been shown (Kimura et al., 2011) and the bioavailability of DA appears to be low (<10%) based on observed excretion of DA into urine following intravenous and oral doses to monkeys (Truelove and Iverson, 1994; Truelove et al., 1997), and recovery of unchanged DA in feces of rodents after oral dose (Iverson et al., 1990). Distribution of DA to the brain and penetration to the developing fetus in pregnant rodents has also been shown after intravenous doses to rodents (Maucher Fuquay et al., 2012a,b). Yet, knowledge of the overall toxicokinetics and target tissue distribution of DA following exposures similar to those that may occur in humans is lacking.

As human and wildlife exposures to DA are exclusively via oral consumption, the aim of this study was to characterize DA toxicokinetics following oral administration to nonhuman primates at levels of exposure near and at the proposed TDI level, and to establish the key toxicokinetic parameters of DA following intravenous and oral dosing to monkeys. Physiologically based pharmacokinetic (PBPK) models of DA toxicokinetics in monkeys and humans were developed to allow simulation of DA toxicokinetics following different routes of administration after acute and chronic exposure.

Materials and Methods

Chemicals and Reagents. DA was purchased from BioVectra (Charlottetown, PE, Canada). Certified calibration solution for DA was purchased from National Research Council Canada (Ottawa, ON, Canada). Optima grade water, methanol, acetonitrile, and formic acid used for bioanalytical assays were purchased from Fisher Scientific (Pittsburgh, PA). β -Glucuronidase from *Escherichia coli* and ammonium acetate were purchased from Sigma-Aldrich (St. Louis, MO).

Animal Studies. The study was conducted in three healthy adult female cynomolgus monkeys between ages 9.8 and 10.3 years and weighing 5.2 ± 1.6 kg (range 3.5–7.2 kg). Animals were housed in the Infant Primate Research Laboratory at the Washington National Primate Research Center. Animals were unsedated for the duration of the study, with unrestricted access to food and water. Animals were fed with Laboratory Diet High Protein Monkey Diet biscuits twice a day, once approximately 2 hours before the DA dose and once approximately 5 hours after the dose of DA. All animal procedure guidelines followed the Animal Welfare Act and the Guide for Care and Use of Laboratory Animals of the National Research Council. All protocols were approved by the University of Washington Institutional Animal Care and Use Committee.

A single intravenous dose of 5 μ g/kg DA dissolved in sterile saline was administered. Blood samples were collected from the saphenous vein before treatment (baseline) and 5, 10, 20, 30, and 45 minutes and 1, 1.5, 2, 3, and 4 hours after treatment. Two repeated intravenous dosing studies were conducted in these animals. During the second intravenous dosing study, urine and feces were collected from cage pans after every blood draw during the study period and at 8, 12, and 24 hours postdose. The DA kinetics were also characterized in these animals following a single oral dose of 0.075 or 0.15 mg/kg DA. DA oral dose was prepared by dissolving 1 mg/ml DA in tap water with 5% sucrose, and the solution was filtered with a syringe filter (0.2 μ M, 25 mm) before use. The dose was given to animals without restraint. Blood samples were collected at baseline and at 1, 1.5, 2, 3, 5, 8, 12, 16, 24, and 48 hours postdose. Urine was collected from cage pans after every blood draw for 24 hours during the study with 0.075 mg/kg DA orally. A washout period of at least 2 weeks was given between each exposure.

Blood samples were collected into sodium heparin tubes and centrifuged at 3,000 g for 15 minutes to isolate plasma for further analysis. Plasma, urine, and feces samples were stored at -20°C until analysis. For all studies, the dosing solutions were analyzed for DA content by LC-MS/MS as described below to confirm DA concentrations.

DA Plasma Protein Binding and Blood-to-Plasma Ratio. The protein binding of DA in plasma was determined by ultracentrifugation using plasma samples from six female cynomolgus monkeys. Three of these monkeys were dosed with 0.15 mg/kg DA orally, 4–6 hours prior to blood sampling, allowing determination of plasma protein binding in exposed animals at physiologically relevant concentration (1–10 nM). The other three monkeys were unexposed, and the plasma from these animals was spiked with 100 nM DA. Plasma from each animal was aliquoted into six tubes with 100 μ l plasma in each tube. Three of these plasma samples were incubated at 37°C for 90 minutes and, meanwhile, another three samples were ultracentrifuged at 451,268 g for 90 minutes at 37°C . After ultracentrifugation, the supernatant was collected and prepared together with incubated plasma samples using the method described below for LC-MS/MS analysis. The unbound fraction in plasma ($f_{u,p}$) was determined as DA concentration measured in the supernatant divided by the DA concentration in the incubated plasma samples. The protein binding of DA in human plasma at 100 nM DA was determined similarly by ultracentrifugation using pooled plasma from eight healthy adult subjects.

The blood-to-plasma concentration ratio of DA was measured as previously described (Jing et al., 2017) in fresh blood from six female cynomolgus monkeys. As described above, three monkeys were dosed with DA and blood-to-plasma concentration ratio was measured in the collected fresh blood, with DA distribution reflecting that obtained after exposure to DA. Fresh blood from the other three unexposed monkeys was spiked with DA to 100 nM final concentration in whole blood. Samples were mixed, aliquoted into four 700 μ l aliquots, and incubated at 37°C for up to 2 hours with aliquots removed at 10 and 30 minutes and 1 and 2 hours. At each time point, 60 μ l of blood in triplicate was removed, and protein was precipitated with 60 μ l methanol. The remaining 500 μ l of blood was centrifuged at 1,000 g for 10 minutes at 4°C to pellet red blood cells and isolate plasma. After centrifugation, 60 μ l of plasma was added to 60 μ l of methanol (in triplicate aliquots), and the samples were prepared as described below and analyzed by LC-MS/MS. The blood-to-plasma concentration ratio of DA (100 nM) was measured using identical methods in fresh human blood.

Analysis of DA Concentrations in Biological Samples by LC-MS/MS. For DA measurements in plasma, 60 μ l of methanol was added to 60 μ l plasma, and the samples were centrifuged at 16,100 g for 40 minutes, set at 4°C for 30 minutes, and centrifuged again at 16,100 g for 30 minutes. The supernatant was collected for analysis. For plasma samples that had concentrations beyond 40 ng/ml based on initial analysis, the supernatant was diluted twofold with water for analysis. For DA measurements in urine, 60 μ l of methanol was added to 60 μ l of urine, the samples were centrifuged at 16,100 g for 20 minutes, and supernatant was collected and diluted 10-fold with water for analysis. For urine samples that had DA concentrations above the range of standard curves after this dilution, the supernatant was collected and diluted 50-fold with water for analysis. Samples that had undetectable/unquantifiable concentrations with 10-fold dilution were prepared with addition of 60 μ l of methanol to 60 μ l urine. These samples were analyzed by LC-MS/MS without further dilution. Standard curves were prepared the same way as the urine samples. For DA measurements in feces, 1 g of feces was first homogenized with 3 ml of water using Omni tissue homogenizer

TABLE 1
Summary of input parameter values for DA PBPK model in monkeys

Parameters	Input Values	Reference/Comment
Molecular weight (g/mol)	311.33	PubChem
logP _{ow}	-0.23	Drug bank
Compound type	Ampholyte	
pK _a 1	4.75	Walter et al. (1992)
pK _a 2	10.6	Walter et al. (1992)
Blood-to-plasma ratio	0.615	Simcyp default value
f _{u,p}	1.0	Measured
Absorption	ADAM	
F _a	0.07	Predicted
P _{eff} (10 ⁻⁴ cm/s)	0.018	Predicted
f _{u,gut}	1	Predicted
Distribution	Full PBPK model	
V _{ss} (l/kg)	0.15	Measured
K _p – brain	0.066	Maucher-Fuquay et al. (2012a)
K _p – kidney	0.46	Funk et al. (2014)

Elimination		
Renal clearance [(ml/min)/kg]	0.98	Measured
CL _{int} (Hep) (μl/min)/10 ⁶ cells ^a	0.48	Assigned (back-calculated from nonrenal clearance)

^aThis value is used to reflect biliary secretion of DA in hepatocytes based on predicted in vivo biliary clearance of 65 (ml/h)/kg. The model cannot differentiate possible metabolism and biliary secretion, and this value should be considered as clearance via other pathways.

(Omni International, Kennesaw, GA). After homogenization, 60 μl of methanol was added to 60 μl of sample, and the mixture was centrifuged for 20 minutes at 16,100 g. The supernatant was collected for LC-MS/MS analysis.

Standard curves were prepared using blank monkey plasma spiked with DA at concentrations of 0.6–40 ng/ml (2–128 nM), blank monkey urine spiked to concentrations 16–996 ng/ml (50–3200 nM) of DA, and blank monkey feces spiked to concentrations 6–103 ng/ml (20–332 nM) of DA. A separate plasma standard curve at 6–199 ng/ml (20–640 nM) of DA was prepared for samples exceeding concentrations of 40 ng/ml. These samples were diluted as described above for high concentration samples. In addition, standard curves for urine analysis were prepared at concentrations of 124–3985 ng/ml (400–12,800 nM) for 1:50 dilution and 0.6–40 ng/ml (2–128 nM) for undiluted samples. All standard curves had ≥6 concentrations of DA. Low, middle and high concentration quality control (QC) samples that were close to the lowest, middle, and highest concentration within the standard curve were extracted along with standard curves and also included in all analyses. Low, middle, and high QC samples were at DA concentrations of 0.9, 7, and 30 ng/ml (3, 24, and 96 nM) for plasma measurements; 16, 156, and 623 ng/ml (50, 500, and 2000 nM) for urine measurements; and 6, 31, and 62 ng/ml (20, 100, and 200 nM) for feces measurements. Uniform weighing was used for all standard curves.

To determine the potential metabolic conjugation of DA in vivo, urine samples were analyzed with and without β-glucuronidase hydrolysis treatment. Briefly, each urine sample was divided into three 200 μl aliquots. Ammonium acetate (46.1 μl; 1 M) and 40 U β-glucuronidase (6.1 μl of 6.5 U/μl in 100 mM ammonium acetate) were added to 200 μl urine and incubated at 37°C for 24 hours. To compare with the samples treated with β-glucuronidase, 52.2 μl ammonium acetate (1 M) was added to an additional 200 μl aliquot of the urine sample and incubated at 37°C for 24 hours. To confirm the stability of DA in this assay, 52.2 μl ammonium acetate (1 M) was added to another 200 μl urine sample and stored at -20°C until analysis. After 24 hours, samples were prepared as described above for analysis by LC-MS/MS.

DA concentrations in plasma samples were measured by LC-MS/MS, using AB Sciex 5500 qTrap Q-LIT mass spectrometer (AB Sciex, Foster City, CA)

equipped with an Agilent 1290 UHPLC (Agilent, Santa Clara, CA) and a Synergi Hydro-RP 100 Å LC Column (2.5 μm, 50 × 2 mm; Phenomenex, Torrance, CA). Compound-dependent MS parameters used for detection of DA were collision energy 26, collision cell exit potential 10, declustering potential 100, and entrance potential 10. Gradient elution with a flow rate of 0.5 ml/min using (A) water with 0.1% formic acid and (B) 95% acetonitrile with 5% water and 0.1% formic acid was used. The gradient was from an initial 95% A for 1 minute to 0% A over 3 minutes and then to 95% A for 3 minutes. Analytes were detected using positive ion electrospray ionization mode. MS/MS transition monitored for DA was m/z 312.2 > 266. DA in the dosing solutions and in urine and feces samples was measured by LC-MS/MS, using AB Sciex 4500 mass spectrometer (AB Sciex) equipped with a Shimadzu UFLC XR DGU-20A5 (Shimadzu Scientific Instruments, Columbia, MD) and a Synergi Hydro-RP 100 Å LC Column (2.5 μm, 50 × 2 mm; Phenomenex). Compound-dependent mass spectrometer parameters used for detection of DA were collision energy 20, collision cell exit potential 10, declustering potential 51, and entrance potential 10. Gradient elution and MS/MS transitions monitored for DA were as described above. Samples were kept in the autosampler at 4°C and 10 μl of sample was injected for analysis.

Pharmacokinetic Analysis. Pharmacokinetic parameters including area under the plasma concentration time curve (AUC), volume of distribution at steady state (V_{ss}), systemic clearance (CL), half-life (t_{1/2}) maximum plasma concentration (C_{max}), time to reach C_{max}, and linear terminal slope were estimated by standard noncompartmental analysis using Phoenix (St. Louis, MO). The geometric mean values are reported for all pharmacokinetic parameters except C_{max} which is reported as arithmetic mean. AUC was calculated by the linear log trapezoidal method for iv dosing data and linear trapezoidal method for oral dosing data and extrapolated to infinity using the determined linear terminal slope (from last five to seven time points in intravenous studies and three to five time points in oral studies) and last observed plasma concentration. Absolute bioavailability (F) was calculated using equation:

$$F = \frac{AUC_{oral}}{AUC_{iv}} \times \frac{Dose_{iv}}{Dose_{oral}}$$

Renal clearance (CL_R) after intravenous and oral dose was obtained using equation:

$$CL_R = \frac{A_{e,0-24}}{AUC_{0-24}}$$

in which $A_{e,0-24}$ is the amount of DA excreted in urine over 24 hours after intravenous or oral dose and the AUC_{0-24} is the AUC over the 24-hour interval after intravenous or oral dose.

Creatinine clearance (CL_{cr}) in the monkeys was calculated using equation:

$$CL_{cr} = \frac{dA_e}{C}$$

in which A_e is the amount of creatinine excreted in urine over a 4-hour interval (dt) and C is the concentration of creatinine measured in plasma. Blood and urine samples for creatinine clearance measurement were collected before the DA intravenous dose. Blood and urine creatinine concentrations were measured by clinical assays at Department of Laboratory Medicine, University of Washington Medical Center.

PBPK Model of DA disposition in Monkeys. A PBPK model of DA was constructed as a full PBPK model using Simcyp Monkey version 16 (Certara, Sheffield, UK). This model is based on cynomolgus monkey physiology without any sex differences in physiological parameters, i.e., the simulation results are independent of sex. The absorption kinetics of DA were simulated with advanced dissolution, absorption, and metabolism (ADAM) model. In brief, the fraction absorbed (F_a) and F were predicted using mechanistic P_{eff} model with scaling factor of 0.45 applied to the P_{eff} predicted from physicochemical parameters for each part of the intestine, to account for the multiple charges in DA molecule that could not be included in the prediction. For DA distribution, a full PBPK model was used. A K_p value for brain was assigned according to the reported AUC_{brain}/AUC_{plasma} ratio in pregnant rats (Maucher Fuquay et al., 2012a). For kidney, liver,

and heart, K_p values were estimated based on the reported concentrations in mice (Funk et al., 2014). K_p values for the rest of the organs were independently predicted in Simcyp using the method described by Rodgers and Rowland (2006) with application of a K_p scalar (0.23, Table 1) to obtain measured V_{ss} that was consistent with the intravenous study. The elimination of DA was characterized using the measured systemic clearance after intravenous dosing [124 (ml/h)/kg, range 87–218 (ml/h)/kg]. The geometric mean renal clearance based on all the animals in all the study days [59 (ml/h)/kg, range 21–152 (ml/h)/kg] was used in the model. The rest of the systemic clearance [65 (ml/h)/kg] was assigned as biliary clearance based on lack of observed metabolism of DA, and the detection of unchanged DA in the feces of monkeys after intravenous dosing and in bile of marine mammals. It is important to note that it is possible DA is also metabolized, but as the current data cannot differentiate between biliary clearance and metabolism either by gut microbiome or by the monkey enzymes, only biliary clearance was included to reflect clearance by other pathways. The biliary clearance per hepatocyte was back-calculated using retrograde scaling. The percentage available for reabsorption was set as 100%, and a sensitivity analysis was conducted for values between 0% and 100%. The model was found to be insensitive to this value. The details of the model input parameters are listed in Table 1, and representative model output files are included as Supplemental Material. The model acceptance criterion was set as ≤ 2 -fold difference between the mean simulated values and observed mean values for AUC. The predicted variability in DA disposition was simulated using the range of observed renal clearance values in this study, as the Simcyp monkey model does not allow simulation of population variability in renal or biliary clearance.

The DA PBPK model was tested by simulating DA disposition in monkeys following intravenous and oral dosing and comparing the simulated results with the in-house toxicokinetic data and the reported data from literature following higher doses of DA to monkeys. In all the simulations, renal clearance values were scaled to the reported body weights of the monkeys in the observed studies. The observed concentration-time profiles from prior publications reporting DA plasma

Fig. 2. Detection of domoic acid (DA) by LC-MS/MS in monkey plasma and urine samples. (A) Blank plasma (B) Plasma sample spiked with 0.6 ng/ml (2.0 nM) DA, (C) Detection of DA in a plasma sample collected 24 hours after dosing with 0.15 mg/kg DA orally. The detected concentration of DA is 2.0 ng/ml (6.3 nM). (D) Blank urine. (E) Detection of DA in a urine sample spiked with 1.6 ng/ml (5.0 nM) DA. (F) Detection of DA in a urine sample collected 24 hours after a 0.15 mg/kg oral DA dose. The concentration of DA is 3.7 ng/ml (11.8 nM). Samples were prepared and analyzed as described in *Materials and Methods*.

Fig. 3. Toxicokinetics of DA in monkeys ($n = 3$) following intravenous and oral administration. (A) Mean plasma concentration-time profile of DA following a single intravenous dose of 5 µg/kg DA. Each data point represents the mean and S.D. of the plasma concentrations measured in two different studies in three animals. (B) Time course of DA excretion into urine following intravenous dosing. The percentage of the intravenous dose of DA (5 µg/kg) excreted in the urine as a function of time is shown. Each data point is the mean and S.D. of three animals. (C) Mean plasma concentration versus time curves of DA following a single oral dose of 0.075 and 0.15 mg/kg DA. Each data point represents the mean and S.D. of three monkeys. (D) Time course of DA excretion into urine following oral dose of 0.075 mg/kg DA. The percentage of oral DA dose excreted in the urine as a function of time is shown as mean and S.D. of three animals.

concentrations in cynomolgus monkeys (Truelove and Iverson, 1994; Truelove et al., 1997) were digitized using Plot Digitizer software (<http://plotdigitizer.sourceforge.net>). For each study, Simcyp species representative individuals were simulated at fed condition using observed range of renal clearances to represent population variability. Sensitivity analysis was done on biliary clearance ranging from 0.23 to 0.53 (µl/min)/million cells by comparing first-order absorption kinetics and ADAM model and fed and fasted conditions. With the exception of fed versus fasted conditions, the model was found to be sensitive to all of the above parameters.

PBPK Model of DA disposition in Humans. A PBPK model of DA disposition in humans was constructed as a full PBPK model using Simcyp version 16 (Certara). The model was based on the developed cynomolgus monkey model using body weight-scaled physiology, renal clearance, and biliary clearance. The absorption kinetics of DA were simulated with human ADAM model. The predicted permeability values corresponded to those used in the monkey model with predicted mechanistic P_{eff} values and the same scaling factor of 0.45. For DA distribution, the K_p values applied to the monkey tissues were also applied in the human model. Both biliary secretion and renal clearance were incorporated in the model. For biliary clearance, the same CL_{int} value in microliters per minute per 10^6 cells was used in the human model and the monkey model. Human renal clearance value was set as 38% of GFR based on the data obtained in the monkeys. No model acceptance criterion was set, as no data exist of DA disposition in humans. DA disposition in humans was simulated in 100 healthy individuals (age: 18–65, average body weight: 80.7 kg, 34% female) using the TDI dose (0.075 mg/kg) and the estimated dose range (0.9–4 mg/kg) in

the Canadian poisoning event. A representative model output file is included as Supplemental Material.

Results

Development of a Sensitive and Specific LC-MS/MS Method to Measure DA in Biological Samples. To measure DA in biological samples including plasma and urine following intravenous and oral administration at a dose level near or at the proposed TDI, a sensitive LC-MS/MS method was developed and validated. DA was detected in monkey plasma and urine using this method and the chromatograms of DA in the biological matrices are shown in Fig. 2. The assay was validated according to the published guidelines for bioanalytical method validation (Shah et al., 2000; Viswanathan et al., 2007). The lower limits of quantification (LLOQ) in plasma and urine were 0.6 ng/ml (2 nM) and 1.6 ng/ml (5 nM), respectively, based on signal-to-noise ratio >9 and interday CV% < 15%. The accuracy and CV% values of QC samples were <15% at all concentrations. The assay was determined sensitive enough to measure DA concentrations in plasma following oral exposures at the proposed TDI level of DA.

Toxicokinetics of DA Following Single Intravenous and Oral Doses. The toxicokinetics of DA following intravenous and oral administration was studied in three female monkeys. Following an

TABLE 2

Observed and predicted toxicokinetic parameters of DA in monkeys after single intravenous doses

Observed values are reported as geometric mean $\pm$ S.D. The predicted population representative values simulated using the PBPK model are shown together with the predicted range of values included in parentheses.

PK Parameter	Observed 5 µg/kg intravenously	Predicted 5 µg/kg intravenously	Observed 50 µg/kg ^a intravenously	Predicted 50 µg/kg intravenously
AUC _{0-∞} [(h·ng)/ml]	40 $\pm$ 24	40 (23–58)	700 $\pm$ 334	403 (230–578)

TABLE 3

Observed and predicted toxicokinetic parameters of DA in monkeys after single oral doses

Observed values are reported as geometric mean ± S.D except for C_{max} which is the arithmetic mean and S.D. The predicted population representative value simulated using the PBPK model is shown together with the predicted range of values included in parentheses.

PK Parameter	Observed 0.075 μg/kg oral	Predicted 0.075 μg/kg oral	Observed 0.15 μg/kg oral	Predicted 0.15 μg/kg oral
$AUC_{0-\infty}$ [(h·ng)/ml]	39 ± 14	45 (25–66)	93 ± 45	90 (51–132)
C_{max} (ng/ml)	1.9 ± 1.5	4.4 (2.8–5.7)	5.3 ± 3.4	8.8 (5.6–11.5)
$t_{1/2}$ (hours)	11.3 ± 2.4	9.3 (9.1–9.5)	9.8 ± 5.9	9.3 (9.1–9.5)
F (%)	6 ± 4	7.5	7 ± 5	7.5

intravenous dose of 5 μg/kg DA, DA had a systemic clearance of 124 ± 71 (ml/h)/kg ($n = 6$) and a short elimination half-life of 1.2 ± 1.1 hours (Fig. 3A; Table 2). On average, 42% ± 11% ($n = 3$) of the DA dose was recovered in urine over 24 hours after the intravenous dose. Based on urinary excretion (Fig. 3B), the renal clearance of DA in these animals

was 36 ± 30 (ml/h)/kg, which is 29% of the mean systemic clearance and 23% of the creatinine clearance [155 ± 55 (ml/h)/kg] in these monkeys. This suggests significant reabsorption of DA in the kidney, and potential other elimination routes of DA including biliary secretion. In accordance with some biliary secretion of DA, DA was also detected

Fig. 4. Predicted and observed plasma concentration-time profiles of DA in monkeys. The solid line in each panel depicts the mean simulated concentrations of DA, the dashed lines depict the variability estimated from the observed range of renal clearances, and the black circles show the observed data. The simulated doses were (A) 5 μg/kg DA intravenously, (B) 50 μg/kg DA intravenously (Truelove and Iverson, 1994), (C) 0.075 mg/kg DA orally, (D) 0.15 mg/kg DA orally and (E) 0.5 (mg/kg)/day DA orally for 15 days (Truelove et al., 1997). In (B) *denotes time points in which the plasma concentration in two animals was reported to be below detection and hence not reported. In (C) and (D) *denotes a time point in which DA concentration in one animal was below detection limit and hence data for this animal are not shown.

Fig. 5. Predicted and observed time course of DA excretion into urine in monkeys following intravenous and oral dosing. The solid line in (A–C) represents the simulated mean, population representative, cumulative % of the administered dose excreted in urine. The dashed lines in each panel show the simulated range of cumulative % of the administered dose excreted based on variability in renal clearance. The circles show the observed data from the current study [(A) and (C): 5 µg/kg DA intravenously and 0.075 mg/kg DA orally, respectively], and from the previous 50 µg/kg DA intravenous dosing. (Truelove and Iverson, 1994) (B) and 0.5 mg/kg per day DA oral dosing studies (Truelove et al., 1997) (D). In (D), the % of the oral dose excreted into urine over a dosing interval at steady state and the dashed lines show the predicted range at steady state. The mean observed values for cumulative % excreted in urine were 42% in (A), 71% in (B), 4% in (C), and 6% in (D). In comparison, the simulated % excreted in urine were 47% in (A), 47% in (B), 3.5% in (C), and 3.5% in (D).

in feces after intravenous dosing at small and variable amounts (data not shown), and the highest DA concentration in feces was 72 ng/g at 0.5 hours post-intravenous dose. Based on DA detection in feces, the maximum total amount of DA eliminated in 24-hour feces was calculated as 5% of the intravenous DA dose. Treatment of urine with β -glucuronidase to test potential glucuronidation of DA *in vivo* did not result in an increase in DA concentration (data not shown).

Administration of single oral doses of DA to the same monkeys at 0.075 and 0.15 mg/kg showed flip-flop kinetics with an absorption rate constant smaller than the elimination rate constant (Fig. 3C). Following oral administration of 0.075 mg/kg DA (proposed TDI), maximum DA concentration of 1.9 ± 1.5 ng/ml was reached at approximately 13 ± 5 hours postdose. A maximum DA concentration of 5.3 ± 3.4 ng/ml was reached at 6 ± 2 hours after 0.15 mg/kg oral dose of DA (twofold of proposed TDI). The terminal half-life of DA was 11.3 ± 2.4 and 9.8 ± 5.9 hours following oral dosing of 0.075 and 0.15 mg/kg DA, respectively (Table 3). Based on the pharmacokinetic analysis, the eightfold longer half-life after oral dosing when compared to intravenous dosing indicated flip-flop kinetics with elimination rate constant (k) of 0.5 ± 0.2 hour⁻¹ and absorption rate constants (k_a) of 0.06 ± 0.01 and 0.07 ± 0.03 hour⁻¹ following 0.075 and 0.15 mg/kg oral doses, respectively. The oral clearances of DA were 2.0 ± 0.7 and 1.6 ± 0.9 (l/h)/kg after single oral doses of 0.075 and 0.15 mg/kg DA, respectively. Based on the intravenous and oral dosing data, the absolute oral bioavailability of DA was calculated to be $6\% \pm 4\%$ and $7\% \pm 5\%$ after single doses of 0.075 and 0.15 mg/kg DA, respectively. After oral

administration of 0.075 mg/kg DA, $4\% \pm 2\%$ of the DA dose was recovered in urine over 24 hours (Fig. 3D). The renal clearance of DA measured after oral dosing was 96 ± 47 (ml/h)/kg, which was 77% of the systemic clearance of DA after intravenous dosing [124 ± 71 (ml/h)/kg] and 62% of the creatinine clearance [155 ± 55 (ml/h)/kg] in these monkeys.

Simulation of DA Disposition in Monkeys Using PBPK Modeling. A PBPK model of DA disposition in monkeys was developed based on obtained experimental and literature data. To develop the PBPK model, the unbound fraction of DA in plasma and the blood-to-plasma concentration ratio of DA were measured. No binding of DA was observed in monkey or human plasma and the unbound fraction was determined to be 1.0. Blood-to-plasma ratio of DA measured in blood from monkeys dosed with DA was 0.59 ± 0.05 . The average hematocrit value for these monkeys was 0.44 ± 0.05 . The blood to plasma ratio measured in spiked blood samples at 100 nM showed consistent values during the time of incubation with average value of 0.56 ± 0.02 . The average hematocrit value for these monkeys was 0.45 ± 0.01 . Blood-to-plasma ratio of DA measured in human blood showed consistent values during the incubation with average value of 0.51 ± 0.01 . These results indicated no partitioning of DA into red blood cells. As the blood-to-plasma ratio is dependent on hematocrit of the individual, a blood-to-plasma ratio of 0.615 was used in the monkey PBPK model based on the defined hematocrit in the monkeys and assuming no blood cell partitioning of DA. The final model parameters are shown in Table 1.

Fig. 6. Simulated concentration-time profiles of DA in monkey brain and kidney. (A) Predicted brain concentration versus time curves for DA following 0.005 mg/kg i.v. (dashed line) and 0.075 mg/kg oral (solid line) doses of DA. (B) Predicted kidney concentration versus time curves for DA following 0.005 mg/kg i.v. (dashed line) and 0.075 mg/kg oral (solid line) doses of DA. (C) Predicted brain concentration versus time curve for DA following 0.05 mg/kg i.v. dose of DA. Areas under the concentration curves (AUC) are shown for each simulation. Predicted brain $C_{\max}$ values were 4.2 ng/ml after 0.005 mg/kg intravenous dosing, 0.3 ng/ml following oral 0.075 mg/kg dosing (A), Predicted kidney $C_{\max}$ values were 32 ng/ml after 0.005 mg/kg intravenous dosing, and 2.0 ng/ml following 0.075 mg/kg oral doses (B). The predicted brain $C_{\max}$ was 41.6 ng/ml following intravenous dose of 0.05 mg/kg DA (C).

To test the developed DA PBPK model, DA disposition was first simulated in monkeys following administration of single intravenous doses of 5 and 50 $\mu\text{g/kg}$ DA, and the simulations were compared with

the observed plasma concentration data obtained in this study and in the previously published study (Truelove and Iverson, 1994) (Fig. 4, A and B; Table 2). The simulated AUC, CL, and CL_r were all within twofold (between 0.6- and 1.7-fold) of the observed data in the two intravenous dosing studies conducted with a 10-fold range in DA doses and in two different laboratories. DA disposition was also simulated in monkeys following single and multiple oral doses using the developed ADAM model for DA absorption. The simulated AUCs for DA all met the acceptance criteria for the model and were within twofold (1- and 1.2-fold) of the observed data after single oral doses of 0.075 and 0.15 mg/kg DA (Fig. 4, C and D; Table 3). The PBPK model predicted the flip-flop kinetics of DA with a 12-fold longer simulated half-life after oral dosing than after intravenous dosing. The predicted terminal half-life (absorption half-life) was within 0.8-fold of the observed. In addition to the current study data, the plasma concentrations of DA following 15 days of oral doses of 0.5 (mg/kg)/day DA were also simulated in accordance with the dosing in the prior study (Truelove et al., 1997), which measured single time point concentrations of DA following multiple oral doses (Fig. 4E). The PBPK model captured the multiple dose pharmacokinetics, predicting the single time point plasma concentrations of DA within the twofold criterion (Fig. 4E). The simulation accuracy of urinary excretion of DA was also evaluated. The excretion of DA into urine as a function of time was compared with the data collected in this study and in previously reported studies (Fig. 5). Overall the mean simulated data of DA dose recovery in urine after both intravenous and oral dosing were within twofold of the mean observed data, although interindividual and interday variability within an individual could be over twofold in the observed data.

The predominant sites of DA toxicity appear to be the brain and possibly the kidney. Therefore, the concentration-time curves of DA in the brain and kidney were simulated using the developed PBPK model that incorporated the K_p values for brain and kidney estimated from literature tissue partitioning data. As shown in Fig. 6A, following a single intravenous dose of 5 $\mu\text{g/kg}$ DA, DA is predicted to rapidly distribute into the brain. Following a single oral dose of 0.075 mg/kg DA, the maximum concentration in the brain is predicted to be reached 3 hours postdose, with prolonged DA exposure in the brain mimicking the flip-flop kinetics observed in plasma. In fact, despite the initial much higher brain concentrations of DA after intravenous dosing, the simulated brain concentrations of DA at later time points were higher following oral dosing than after intravenous dosing. Similarly, the distribution pattern of DA was also simulated in kidney following intravenous and oral doses (Fig. 6B). The kidney concentration-time profiles were similar to those simulated for the brain. High kidney concentrations were reached rapidly following intravenous dosing and slowly after oral dosing, with prolonged exposure in the kidney after oral exposure. Overall, the predicted kidney tissue concentrations were higher than those predicted for the brain. The simulated brain-to-plasma and kidney-to-plasma AUC ratios were 0.066 and 0.46, respectively, reflecting the K_p values observed in rodents. To explore the brain concentration versus time profile of DA following dosing that results in signs of toxicity, the brain concentrations of DA were also simulated in monkeys after 0.075 mg/kg i.v. (Fig. 6C). These simulations predicted a peak brain concentration of 41.6 ng/ml and concentrations above 10 ng/ml up to 1 hour. This suggests that in monkeys brain concentrations above 10 ng/ml correspond to acute toxicity, as the vomiting in monkeys after 0.075 mg/kg i.v. dose of DA was restricted to the first 9–62 minutes after dosing (Truelove and Iverson, 1994).

Simulation of DA Disposition in Humans Using PBPK Modeling. A PBPK model of DA toxicokinetics in humans was developed based on the nonhuman primate model. DA disposition in humans following exposures at the current acute reference dose and at exposures similar to

Fig. 7. Simulated concentration-time profiles of DA in humans. (A and C) Predicted plasma (A) and brain (C) concentration versus time curves for DA following consumption of 0.075 mg/kg of DA by mouth. (B and D) Predicted plasma (B) and brain (D) concentration versus time curves for DA following consumption of 0.9–4.1 mg/kg of DA orally, the exposure estimated in the DA toxicification incident. Dotted lines depict the 95th and 5th percentile obtained from the virtual population. The area under the concentration curve (AUC) values are reported in each respective panel. Predicted C_{max} are (A) 1.8, (B) 21.8 and 99.3 ng/ml following 0.9 and 4.1 mg/kg of DA doses, respectively, (C) 0.1 mg/ml, and (D) 1.4, and 6.6 ng/ml following 0.9 and 4.1 mg/kg of DA doses respectively.

those estimated in the DA outbreak in Canada in 1987, was simulated using the human PBPK model. The variability in DA disposition in human population was simulated using the population variability in Simcyp library. The simulated plasma and brain concentration-time curves are shown in Fig. 7. At TDI (0.075 mg/kg orally), the exposure in humans is predicted to be about 30%–40% of that observed in monkeys exposed to the same per kilogram dose. Similar to the monkeys, DA exposure in humans after an oral dose was predicted to be prolonged due to the flip-flop kinetics. The brain concentrations of DA in humans were simulated for the doses of 0.9–4.1 mg/kg DA corresponding to the estimated consumption in the DA outbreak in Canada (Perl et al., 1990). The predicted brain concentrations ranged from 1.4 to 6.6 ng/ml (Fig. 7) and were similar (within 0.2- to 1-fold) to the simulated threshold brain concentrations in monkeys experiencing DA toxicity.

Discussion

Over recent decades, toxic algal blooms have increased, resulting in increased risk of DA poisoning in marine mammals and humans who consume contaminated seafood (McCabe et al., 2016). Oral acute reference doses and TDI of DA have been proposed based on toxicity studies in nonhuman primates and estimated lowest observed adverse effect levels in humans (Costa et al., 2010). However, these values were derived without knowledge of DA concentrations in humans, or characterization of the absorption kinetics of DA in humans or nonhuman primates after oral doses. This lack of information is largely due to the limited number of bioanalytical methods to measure DA at low levels in biological samples. In fact, the only plasma concentrations available in a model species after oral exposure are from monkeys dosed at 0.5–0.75 (mg/kg)/day orally (Truelove et al., 1997; Fig. 4). In rats, after oral administration, DA plasma concentrations were below the LLOQ in all samples analyzed (Iverson et al., 1990; Truelove et al., 1996). Existing LC-MS/MS methods lack sufficient sensitivity (LLOQ > 7 ng/ml) compared with ELISA (LLOQ = 0.4 ng/ml) (Frame and Lefebvre, 2013) and require large sample volumes (>500 μ l) (Wang et al., 2012). To allow quantification of DA in biological samples following oral doses similar to current no observed adverse effect level doses, we developed an LC-MS/MS method with sensitivity similar to

the ELISA. This method will be useful for future evaluation of DA kinetics and exposures in experimental animals, wildlife, and in humans consuming potentially contaminated seafood.

This study provides the first characterization of the absorption kinetics of DA following oral exposure in mammals and shows that DA is subject to pronounced flip-flop kinetics with a slow absorption from the gut. Due to the flip-flop kinetics, the terminal half-life of DA following oral exposure is prolonged compared to what would have been expected from the intravenous data. The bioavailability of 7% determined in this study is in excellent agreement with the previous work suggesting <10% bioavailability of DA (Truelove and Iverson, 1994; Truelove et al., 1997). This low bioavailability is consistent with the high polarity and fully charged state of DA at physiological pH (Vera-avila et al., 2011) and possible predominantly paracellular absorption of DA. The extent of absorption and the flip-flop kinetics of DA following oral dosing were predicted using the P_{eff} value for DA and the monkey ADAM model in Simcyp. As the mechanistic absorption model predicted DA absorption kinetics in monkeys, a DA PBPK model was developed to predict DA toxicokinetics in humans. The PBPK model predicted flip-flop kinetics for DA also in humans, suggesting a prolonged exposure to DA after consumption of contaminated seafood. Yet, it is likely that uptake and efflux transporters contribute to DA absorption kinetics, which is not captured in the current model. In a prior study, apical-to-basolateral transport of DA in Caco-2 cells was shown to be decreased by 31.5% when DA was incubated with probenecid (100 mM), a nonspecific inhibitor of anion transport (Kimura et al., 2011), suggesting transporter involvement in the intestinal absorption of DA.

The developed monkey PBPK model was also used to simulate the brain and kidney concentrations of DA following intravenous and oral doses of DA. DA concentrations were previously reported in the kidney, liver, heart, and hippocampus of mice (Funk et al., 2014) and in brain and cerebrospinal fluid in pregnant rats (Maucher Fuquay et al., 2012a). The simulated brain and kidney distribution in monkeys is in excellent agreement with prior data from rats showing rapid distribution of DA into tissues after intravenous dosing (Maucher Fuquay et al., 2012a). The simulated fast distribution to the brain is also in agreement with the fast onset of vomiting (2–14 minutes) in monkeys dosed with 50 μ g/kg intravenously and the duration of the vomiting restricted to the first

9–62 minutes after intravenous dosing (Truelove and Iverson, 1994). The simulated brain concentration-time curves after oral exposure in either monkeys or humans (Figs. 6 and 7) provide insight into the prolonged onset of signs of DA toxicity following consumption of contaminated mussels by humans. In the 1987 DA outbreak, the onset for symptoms after consumption of DA contaminated mussels was between 15 minutes and 38 hours (median 5.5 hours) (Perl et al., 1990). As shown in Figs. 6 and 7, following consumption of DA, the time to reach maximum DA concentrations in the brain is expected to be delayed. The PBPK models predicted similar (within 1- to 5-fold) peak brain DA concentrations in the human poisoning event and as brain threshold concentrations in monkeys dosed intravenously and experiencing DA toxicity. The PBPK models also predicted a much longer duration of exposure in the brain following oral dosing than what is observed after intravenous dosing. This may be important for chronic toxicity of asymptomatic exposures to DA, that lead to the reported sensitization to DA and to epigenetic changes (Hiolski et al., 2014; Lefebvre et al., 2017). However, the current model does not incorporate possible transporter contributions to brain distribution of DA, which requires further study. The DA analogs kainic acid and dehydrokainic acid have been shown to have low blood-brain barrier permeability but not require active transport for uptake to the brain (Gynther et al., 2015). Efflux transporters, such as MRP5 may, however, restrict brain exposure to DA and cause some species differences in brain distribution, as DA and kainic acid have been shown to be substrates for MRP5 (Jansen et al., 2015).

The majority of DA clearance is believed to be via the kidney, because in rats DA is entirely eliminated via the kidney through glomerular filtration (Suzuki and Hierlihy, 1993). Hence, renal impairment has been considered in estimating human safety factors for DA. However, the data presented here and the previous study in cynomolgus monkeys (Truelove and Iverson, 1994) show less than complete urinary recovery (42%–71%) of DA. This suggests that other elimination pathways of DA exist in addition to renal excretion. Biliary secretion by efflux transporters likely contributes to DA clearance. DA was detected in fecal samples in this study after intravenous dosing, and DA has been found in the bile of California sea lions (15–344.7 ng/ml DA) and harbor porpoise (11.7 ng/ml DA) (Rust et al., 2014). In addition, consistent with biliary secretion of DA, the plasma-concentration time curves of DA following oral dosing to monkeys had a characteristic second peak for DA concentrations (around 16–24 hours in Fig. 3C), suggesting some extent of enterohepatic recycling. In rats, probenecid caused a significant increase in plasma DA levels (Robertson et al., 1992) but had no effect on DA renal clearance (Suzuki and Hierlihy, 1993). In mice, probenecid also increased DA concentrations in kidney tissue and serum (Funk et al., 2014). These findings are consistent with hepatic interaction between probenecid and efflux transporters responsible for DA excretion. Further studies are needed to evaluate the quantitative significance of biliary secretion and possible metabolism in DA clearance, and to identify potential transporters responsible for biliary secretion of DA.

The overall renal clearance of DA in monkeys was lower than the GFR, suggesting that, in addition to glomerular filtration, significant DA reabsorption occurs. Due to its high charge state and polarity, passive transcellular reabsorption of DA in the kidney tubule is not expected. Indeed, the renal clearance of DA in the rat has been shown to be similar to the GFR (Suzuki and Hierlihy, 1993). The observation of significant reabsorption of DA in monkeys is consistent with the previous findings after intravenous dosing of DA to monkeys (Truelove and Iverson, 1994). These data suggest that active transport contributes to the reabsorption of DA in monkeys. As the identity and quantitative importance of specific transporters in DA renal clearance is not known,

the observed renal clearance of 0.98 (ml/min)/kg in monkeys was used for the PBPK model. Although the renal clearance and urinary excretion of DA had high inter- and intraindividual variability, the developed monkey PBPK model predicted the urinary excretion of DA following intravenous and oral dosing and single and multiple dose exposures across studies (Fig. 5).

In conclusion, this study shows that DA has pronounced flip-flop kinetics in monkeys following oral dosing, resulting in lower peak concentrations and longer exposures than would be expected based on intravenous kinetics and with rapid absorption. The toxicokinetic data together with the PBPK model strongly suggest that efflux transporters in the liver are an important contributor to DA elimination. The developed PBPK model provides a powerful tool for future evaluation of DA disposition in acute and chronic toxicology studies, and a framework for future exploration of contribution of transporters to DA clearance and distribution to target organs. The monkey PBPK model also provided a basis for a DA PBPK model in humans to support extrapolation of toxicity data between species and exposure levels. The results of this study provide important new information to evaluate exposure-toxicity relationships of DA to aid in assessment of human DA exposure risks in different populations.
