Breast Cancer Resistance Protein and Multidrug Resistance Protein 2 Determine the Disposition of Esculetin-7-O-Glucuronide and 4-Methylesculetin-7-O-Glucuronide

Yuhuan Li, Wenjie Song, Xiaojun Ou, Guangkuo Luo, Yushan Xie, Rongjin Sun, Ying Wang, Xiaoxiao Qi, Ming Hu, Zhongqiu Liu, and Lijun Zhu

ABSTRACT

Esculetin (ET)-7-O-glucuronide (ET-G) and 4-methylesculetin (4-ME)-7-O-glucuronide (4-ME-G) are the main glucuronide of ET and 4-ME, respectively. The disposition mediated by efflux transporters for glucuronide has significant influence on the pharmacokinetic profile and efficacy of bioactive compounds. In the current study, transporter gene knockout mice and Caco-2 cells were used to explore the effects of breast cancer resistance protein (BCRP) and multidrug resistance–associated protein 2 (MRP2) on the disposition of ET-G and 4-ME-G. After oral or i.v. administration of ET and 4-ME, the area under the plasma concentration–time curve from time 0 to the last data point or infinity values of ET, 4-ME, and their glucuronides (ET-G and 4-ME-G) were remarkably and significantly increased in most Bcrp1<sup>−/−</sup> and MRP2<sup>−/−</sup> mice compared with those in wild-type FVB mice (P < 0.05). These results were accompanied with a significant increase of maximum plasma concentration values (P < 0.05). In Caco-2 monolayers, the efflux and clearance rates of ET-G and 4-ME-G were markedly reduced by the BCRP inhibitor Ko143 and MRP2 inhibitor MK571 on the apical side (P < 0.05). In an intestinal perfusion study, the excretion of ET-G was significantly decreased in perfusate and increased in plasma in Bcrp1<sup>−/−</sup> mice compared with those in wild-type FVB mice (P < 0.05). The 4-ME-G concentration was also decreased in the bile in transporter gene knockout mice. ET and 4-ME showed good permeability in both Caco-2 monolayers [apparent permeability (P<sub>app</sub>) ≥ 0.59 × 10<sup>−6</sup> cm/s] and duodenum (P<sub>app</sub> ≥ 1.81). In conclusion, BCRP and MRP2 are involved in excreting ET-G and 4-ME-G. ET and 4-ME are most likely absorbed via passive diffusion in the intestines.

Introduction

Esculetin [6,7-dihydroxy-coumarin (ET)] is a well-known naturally occurring coumarin derivate found in many herbs, such as <i>Fraxinus rhynchophylla</i>, <i>Rehmannia glutinosa</i>, and <i>Artemisia capillaries</i> (Li et al., 2011; Venugopala et al., 2013). ET provides a broad range of pharmacological activities, including antioxidant, anti-inflammatory, antitumor, antiviral, antifungal, and neuroprotective properties (Witacenis et al., 2010; Viana et al., 2012; Wang et al., 2012; Jeon et al., 2015). The 4-methylesculetin [6,7-dihydroxy-4-methylcoumarin (4-ME)], a synthetic coumarin derivate that contains a methyl group at C-4 in ET molecules, has also been extensively investigated because it exhibits various pharmacological functions similar to those of ET (Hajime et al., 2007; Henshekhar et al., 2013; Maistro et al., 2015). Thus, ET and 4-ME, as potential therapeutic agents, have attracted substantial attention from researchers.

The disposition characteristics of bioactive compounds influence their in vivo pharmacokinetics and pharmacodynamics. Elucidation of the disposition characteristics and underlying mechanisms of the disposition of these compounds would provide information to identify potential drug candidates and drug–drug interactions. We have previously demonstrated that the conjugation reactions of ET and 4-ME at the 7-C position generate ET-7-O-glucuronide (ET-G) and 4-ME-7-O-glucuronide (4-ME-G), respectively. This reaction is mediated by

ABBREVIATIONS: 4-ME, 4-methylesculetin; 4-ME-G, 4-ME-7-O-glucuronide; AP, apical; AUC, area under the plasma concentration–time curve; BCRP, breast cancer resistance protein; BL, basolateral; Cl<sub>max</sub>, maximum plasma concentration; CL<sub>e</sub>, clearance; ET, esculetin; ET-G, ET-7-O-glucuronide; F<sub>bio</sub>, bioavailability; F<sub>met</sub>, fraction of the metabolized dose; HBSS, Hanks’ balanced salt solution; IS, internal standard; J, efflux rate; M/P, Metabolite/Parent; MRP, multidrug resistance–associated protein; P<sub>app</sub>, apparent permeability; P<sub>eff</sub>, effective intestinal permeability; UHPLC-MS/MS, ultrahigh-performance liquid chromatography–tandem mass spectrometry.
UDP-glucuronosyltransferase 1A9 and UGT1A6 in human liver and intestinal microsomes (Zhu et al., 2015). The elimination of glucuronides from cells requires the aid of efflux transporters [e.g., breast cancer resistance protein (BCRP)] because these metabolites are too hydrophilic to diffuse across the cellular membrane (Jeong et al., 2005b; Wang et al., 2006). The clinical evidence of impaired BCRP activity produced increased systemic exposure of gefitinib, rosuvastatin, sunitinib, and active metabolite of leflunomide, sulfadiazine, and diflomotecan (Lee et al., 2015). The importance of efflux transporters modulating the glucuronides excretion of bioactive compounds has been demonstrated in wild-type and transporter knockout mice (Ge et al., 2015; Qin et al., 2018). Thus, further investigation into the role of efflux transporters in the excretion of ET-G and 4-ME-G is important to accurately predict their disposition and efficacy in vivo.

BCRP and multidrug resistance–associated protein (MRP2) are ATP-binding cassette transporters that are widely located on the apical (AP) portions of the liver and intestine (Yang et al., 2017). BCRP and MRP2 are likely to excrete compounds with high hydrophilicity such as most conjugation metabolites (glucuronides and sulfates) (An and Morris, 2011; Zheng et al., 2016). The inhibition or deficiency of BCRP and MRP2 decreases the plasma exposure of parent drugs and their metabolites, which could result in reduced efficacy, although these drugs have good absorption characteristics (Pan et al., 2015; Kong et al., 2016). Transporter (e.g., P-glycoprotein, BCRP, and MRP2) gene knockout models, in which glucuronidation activities remain unaltered, are commonly used in understanding transporter-limited or transporter-mediated drug absorption, distribution, and excretion (Klaassen and Lu, 2008; Zamek-Gliszczynski et al., 2012, 2013). Mouse Bcrp1 protein and human BCRP protein are structurally and functionally similar. They share 87% sequence homology and efflux identical substrates (Natarajan et al., 2011). Murine in vivo models harboring Bcrp1 gene knockouts in Caco-2 cells, which express various phase I and phase II enzymes as well as ATP-binding cassette transport proteins such as P-glycoprotein, BCRP, and MRPs (e.g., MRP1, MRP2, MRP3, and MRP4), are frequently used to study human intestinal absorption, metabolism, and transport (Ikeda et al., 2008; Meinl et al., 2008; Ming and Thakker, 2010). Inhibition assays in Caco-2 monolayers are also commonly used to identify transporter substrates. Ko143 (at concentrations from 0.5 to 20 μM) was collected by scraping the cut. The blood samples were centrifuged at 11,040 g for 10 minutes. The first and second fractions were discarded.

Materials and Methods

Chemicals and Reagents. ET, 4-ME, ET-G, and 4-ME-G were obtained, as described previously (Zhu et al., 2015). Testosterone [used as internal standard (IS); purity >98%], Ko143, MK571, and Hanks’ balanced salt solution (HBSS; powder form) were purchased from Sigma-Aldrich (St. Louis, MO). Six-well polycarbonate cell culture inserts (with an absorption surface area of approximately 4.2 cm² and a pore size of 3 μm) were obtained from Corning (Corning, NY). Cloned Caco-2 cells (TC7) were provided by M.H. (Department of Pharmaceutical Sciences, College of Pharmacy, University of Houston, TX). All other chemicals and solvents were of analytical grade or better.

Animals. Male wild-type FVB mice (9–11 weeks) were purchased from Vital River Laboratory Animal Technology (Beijing, China). Male Bcrp1−/− mice and Mrp2−/− mice (9–11 weeks old) of a >99% FVB genetic background were purchased from Biomedical Organism Science & Technology Development (Shanghai, China). Mice were kept in an environmentally controlled room (temperature of 25 ± 2°C, relative humidity of 50% ± 5%, and 12-hour dark/light cycle) for at least 1 week before the experiment. The animal experiments used in this study were approved by the Guangzhou University of Chinese Medicine’s Ethics Committee.

Cell Culture. Caco-2 cells were cultured in Dulbecco’s modified Eagle’s medium containing 10% fetal bovine serum, 1% nonessential amino acids, 1% L-glutamine, and 1% antibiotics (penicillin and streptomycin) at 37°C with 5% CO₂. For the transport experiments, 2.5 × 10⁵ cells/well were seeded onto the 4.2-cm² inserts and grown for 19–22 days. Transepithelial electrical resistance values less than 460 Ω/cm² were discarded.

UHPLC-MS/MS CONDITIONS. ET, 4-ME, and their glucuronides (ET-G and 4-ME-G) were separated and quantified using an Agilent UHPLC 1290 Infinity-Triple Quad MS 6460 (UHPLC-MS/MS) equipped with an electrospray ionization source. The chromatographic separation was achieved on a Zorbax C₁₈ column (100 × 3.0 mm²; 1.8 μm; Agilent Technologies, Santa Clara, CA) using a mixture of 0.1% formic acid aqueous solution (A) and methanol (B) as the mobile phase with the following gradient elution: 20% (v/v) B from 0 to 1 minute; 90% B from 3 to 6 minutes; 20% B at 7 minutes; and the post-time was 0.5 minutes. The injection volume was 5 μl, the flow rate was 0.3 ml/min, and the column temperature was maintained at 35°C. The mass spectrometer parameters were as follows: capillary voltage, 4.0 kV; nozzle voltage, 500 V; nebulizer, 45 psi; gas temperature, 300°C with a gas flow of 5 l/min; and sheath temperature, 350°C with a sheath gas flow of 11 l/min.

The optimized fragmentation voltages of ET-G, ET-G, and testosterone (IS) were 90, 100, and 120 V, respectively. Quantification was performed in positive ion and multiple reaction monitoring mode using the following transitions: m/z 179.0→122.9 for ET with a collision energy of 22 eV; m/z 355.0→179.0 for ET-G with a collision energy of 15 eV; and m/z 289.0→97.1 for testosterone with a collision energy of 22 eV. The δ electron multiplier voltage was 250 V, and the cell acceleration voltage of all was 4 V. The method was to waste before 1 minute, then to mass spectrometer.

The optimized fragmentation voltages of 4-ME, 4-ME-G, and testosterone (IS) were 105, 135, and 120 V, respectively. Quantification was performed in positive ion and multiple reaction monitoring mode using the following transitions: m/z 193.0→147.0 for 4-ME with a collision energy of 20 eV; m/z 369.0→193.0 for 4-ME-G with a collision energy of 20 eV; and m/z 289.0→97.1 for testosterone with a collision energy of 22 eV. The δ electron multiplier voltage was 400 V, and the cell acceleration voltage of all was 4 V. The method was to waste before 2 minutes, then to mass spectrometer.

Pharmacokinetic Studies of ET and 4-ME in Wild-Type, Bcrp1−/−, and Mrp2−/− FVB Mice. Mice were fasted for 10 to 12 hours with free access to water before the pharmacokinetics experiments. For oral administration, ET and 4-ME suspensions (1 mg/ml) were prepared with 20% (v/v) hydroxypropyl β-cyclodextrin aqueous solution. Wild-type and transporter knockout FVB mice were orally administered with 10 mg/kg ET (56.14 μmol/kg) or 4-ME (52.03 μmol/kg). For i.v. injection, ET and 4-ME solutions (0.3 mg/ml) were prepared with 5% (v/v) hydroxypropyl β-cyclodextrin aqueous solution. Wild-type and transporter knockout FVB mice were i.v. injected with 2 mg/kg ET (11.23 μmol/kg) and 4-ME (10.41 μmol/kg). Blood samples (approximately 25 μl) were collected from the tail vein and then placed in dried heparinized tubes at 0, 3, 5, 10, 15, 30, 45, 60, 120, 240, 360, 480, 720, and 1440 minutes. The first blood sample was collected by cutting the tail; the following blood samples were collected by scraping the cut. The blood samples were centrifuged at 11,040 for...
8 minutes. The plasma supernatant was removed to a new tube and stored at −80°C until analysis. Plasma samples were prepared by mixing 10 μl plasma sample and 200 μl methanol containing 200 nM IS, followed by vortexing for 3 minutes. The mixture was centrifuged at 19,357 g for 30 minutes. Supernatant (160 μl) was transferred to a new tube and evaporated to dryness in a vacuum drying oven. The residue was dissolved with 80 μl 50% methanol aqueous solution. After centrifugation at 19,357 g for 30 minutes, 10 μl supernatant was injected into the UHPLC-MS/MS for analysis.

The pharmacokinetic parameters, including area under the plasma concentration–time curve (AUC) from time 0 to the last data point or infinity (AUC0–∞, and AUC0–τ), half-life, maximum plasma concentration (Cmax), mean residence time, Vd, and clearance (CL), were analyzed using the noncompartmental model in WinNonlin 3.3 (Pharsight, Mountain View, CA). The AUC0–∞, or AUC0–τ was calculated by the trapezoidal rule–extrapolation method. The average absolute bioavailability (F%) values of ET and 4-ME were determined by using the following formula:

\[
F\% = \frac{AUC_0–τ, p}{AUC_0–τ, i.v.} \times \frac{D_{p.o.}}{D_{i.v.}} \times 100\%
\]  

(1)

where \(\text{AUC}_{0–τ,p}\) and \(\text{AUC}_{0–τ,i.v.}\) represent the average area under the concentration–time curve from zero to infinity after ET (or 4-ME) oral and injection administration, respectively. \(D_{p.o.}\) and \(D_{i.v.}\) represent the dose of ET (or 4-ME) oral and injection administration, respectively.

**Bidirectional Transport Study of ET and 4-ME in Caco-2 Monolayers.**

The transport experiments were conducted, as described previously (Ye et al., 2013). Before the experiment, Caco-2 monolayers were washed thrice with warm HBSS at 37°C. Testing compound (2 ml; 10 μM ET or 4-ME) was loaded on the AP side or BL side of the cell monolayers, and 2 ml blank HBSS was loaded on the other side. In the inhibition experiment, BCRP inhibitor (Ko143, 5 μM) and MRPI inhibitor (MK571, 10 μM) were added to the AP side to determine whether AP efflux transporters (BCRP and MRPI) participate in the efflux of ET, 4-ME, and their glucuronides. Samples (0.5 ml) were collected from both sides of each transwell at designated times (0, 0.5, 1, 1.5, and 2 hours), and the same volume of the testing compound or blank HBSS was immediately replenished. Then 250 μl methanol containing 200 nM IS was added to 500 μl incubation samples to determine the analytes. Cell monolayers were carefully washed thrice and collected into 0.3 ml HBSS at the end of the transport experiment. Cells were ultrasonicated in an ice bath (4°C) for 30 minutes. After centrifugation at 17,949 g for 30 minutes, the supernatant was separated into two aliquots, as follows: one was for measuring protein; the other was prepared for determining cellular ET, 4-ME, and their glucuronides. Samples (0.5 ml) were collected from both sides of each monolayer in WinNonlin 3.3 (Pharsight, Mountain View, CA). The AUC0–τ, or AUC0–τ was calculated by the trapezoidal rule–extrapolation method. The average absolute bioavailability (F%) values of ET and 4-ME were determined by using the following equation:

\[
P_{app} = \frac{dQ/dt}{A_{C0}}
\]  

(2)

where \(dQ/dt\) is the rate of ET and 4-ME transported on the receiver side; \(C_0\) is the initial concentration of compounds on the donor side; and \(A\) is the monolayer growth surface area of 4.2 cm².

The fraction of the metabolized dose (Fmet) was calculated in this study in response to the extent of metabolism in Caco-2 cells by the following equation:

\[
F_{\text{met}} = \frac{\sum \text{metabolite}}{\sum \text{metabolite} + \sum \text{parent compound}}
\]  

(3)

The excretion rate (J) of glucuronide was obtained from the rate of change in the concentration of the substrate (or its metabolite), and this parameter was expressed as a function of time and volume of the sampling chamber (V), as follows:

\[
J = \frac{dc}{dt} \times V
\]  

(4)

The CL of efflux transporter was calculated in this study because the extracellular concentration of glucuronides differed from their intracellular concentration. CL was determined using the excretion rate of glucuronides (J) divided by the intracellular concentration of glucuronides (\(C_{in}\)), as follows:

\[
CL = \frac{J}{C_{in}} = \frac{J_{\text{max}}}{K_m + C_{in}}
\]  

(5)

where \(J_{\text{max}}\) is the maximal excretion rate of glucuronides, and \(K_m\) is the Michaelis constant of glucuronide efflux. To determine \(K_m\), we assumed that the average cytosolic water volume of the cells was 4 μl/mg protein. The intracellular metabolite concentration was calculated from the total amount of intracellular glucuronides divided by the total volume of intracellular protein.

**Perfused Mouse Intestinal Model for Glucuronidation Disposition of ET and 4-ME.** Two segments (upper small intestine and colon) of the mouse intestine were perfused simultaneously with perfusate containing 70 μM ET (or 4-ME) using an infusion pump (model PHD2000; Harvard Apparatus, Cambridge, MA) at a flow rate of 0.167 ml/min. Before the surgery, each mouse was anesthetized with 10 mg/ml urethane (0.03 ml/10 g, i.p.). The mouse intestinal surgical procedures were modified from the rat model previously described (Chen et al., 2003; Jeong et al., 2005a). Briefly, after the mouse was anesthetized, it was put over a heating blanket and under a heating lamp to keep its normal body temperature. Then the mouse abdominal cavity was opened and the duodenum was located as the intestinal segment immediately adjacent to the stomach. First, two cannulae at approximately 10 cm apart were inserted into two ends of the duodenum and secured with suture. Second, the colon inlet cannula was inserted into the colon at approximately 2 cm below the junction, and the outlet cannula was inserted through the anus. After a 30-minute washout period, which is considered to achieve steady-state absorption, perfusate were collected from the outlet cannula every 15 minutes during the 1-hour perfusion period. Perfusion that did not cross the intestinal segments was also collected every 30 minutes as a control. The blood samples were withdrawn from tail vein at the end of the perfusion. The gallbladder was excised, and the bile was collected. The length of the intestine was measured, as described previously (Hu et al., 1998). The effective intestinal permeability (\(P_{et, m}\)) coefficient and absorption amounts of ET and 4-ME and the percentage of glucuronides (ET-G and 4-ME-G) excreted into the perfusate in the mice were measured and calculated, as described previously (Chen et al., 2003; Dai et al., 2015). The exposure of ET-G and 4-ME-G was determined by using the peak area in the perfusion experiment because the commercial source of ET-G and 4-ME-G was unavailable.

**Statistical Analysis.** SPSS 17.0 was used to evaluate significant differences, and unpaired Student’s t test was used to analyze the data. Data were presented as the mean ± S.D. Differences were considered significant at P < 0.05.

**Results**

**Pharmacokinetic Profile of ET and 4-ME in Wild-type, Bcrp1−/−, and Mrp2−/− FVB Mice.** The mean plasma concentration–time curves after the oral administration of 10 mg/kg (56.14 μmol/kg) ET in wild-type, Bcrp1−/−, and Mrp2−/− FVB mice are shown in Fig. 1, A and B, and the pharmacokinetic parameters are shown in Table 1. After oral administration, ET was quickly absorbed and metabolized into ET-G, and lower ET was detected in plasma samples. The AUC0–τ, values of ET and ET-G in wild-type FVB mice were 2.96 ± 0.98 and 306.68 ± 113.93 minutes • μmol/l, respectively, and those in Bcrp1−/− mice were significantly increased to 32.68 ± 14.49 and 1356.30 ± 666.51 minutes • μmol/l, respectively (P < 0.05). The AUC0–τ, value of ET was significantly increased from 2.96 ± 0.98 minutes • μmol/l in wild-type FVB mice to 23.48 ± 9.96 minutes • μmol/l in Bcrp1−/− mice (P < 0.05). The Cmax values of ET and ET-G were also increased from 0.20 ± 0.11 μmol/l in wild-type FVB mice to 8.21 ± 5.78 μmol/l in Bcrp1−/− mice for ET and 2.46 ± 0.36 μmol/l in wild-type FVB mice to 7.58 ± 1.65 μmol/l for ET-G in Bcrp1−/− mice (P < 0.05). The Cmax value of ET in Mrp2−/− mice was more than threefold higher than that in wild-type FVB mice (P < 0.05). The AUC0–τ, ratios of ET-G to ET (Metabolite/Parent AUC ratios, M/P AUC ratios) in wild-type FVB mice, Bcrp1−/− mice, and Mrp2−/− mice were 103.61, 41.50, and 15.98, respectively. The pharmacokinetic profiles after i.v. injection (i.v.) of 2 mg/kg (11.23 μmol/kg) ET are shown in Fig. 1, C and D, and the pharmacokinetic parameters are shown in Table 2. The AUC0–τ, value of ET was significantly increased from 5.88 ± 4.93 minutes • μmol/l in
wild-type FVB mice to 32.04 ± 8.47 minutes • μmol/l in Mrp2$$^{-/-}$$ mice ($P < 0.05$). The AUC$$_{0-\infty}$$ value of ET-G was also significantly increased from 155.76 ± 50.41 minutes • μmol/l in wild-type FVB mice to 259.85 ± 69.20 minutes • μmol/l in Bcrp1$$^{-/-}$$ mice ($P < 0.05$). The average absolute $$\%$$ of ET in wild-type FVB mice, Bcrp1$$^{-/-}$$ mice, and Mrp2$$^{-/-}$$ mice were 10.07%, 17.10%, and 14.66%, respectively. Additionally, the AUC$$_{0-\infty}$$ ratios of ET-G to ET (M/P AUC ratios) in wild-type FVB mice, Bcrp1$$^{-/-}$$ mice, and Mrp2$$^{-/-}$$ mice were 26.50, 6.80, and 4.52, respectively.

The mean plasma concentration–time curves after oral administration of 10 mg/kg (52.03 μmol/kg) 4-ME in wild-type, Bcrp1$$^{-/-}$$, and Mrp2$$^{-/-}$$ FVB mice are shown in Fig. 2. A and B, and the pharmacokinetic parameters are shown in Table 3. The AUC$$_{0-\infty}$$ value of 4-ME in Bcrp1$$^{-/-}$$ mice (193.56 ± 42.58 minutes • μmol/l) was significantly higher than that in wild-type FVB mice (64.23 ± 18.52 minutes • μmol/l) ($P < 0.05$). The AUC$$_{0-\infty}$$ values of 4-ME-G in Bcrp1$$^{-/-}$$ mice (733.70 ± 202.51 minutes • μmol/l) and Mrp2$$^{-/-}$$ mice (535.13 ± 81.20 minutes • μmol/l) were also significantly higher than that in wild-type FVB mice (375.21 ± 114.50 minutes • μmol/l) ($P < 0.05$). The AUC$$_{0-\infty}$$ ratios of 4-ME-G to 4-ME (M/P AUC ratios) in wild-type FVB mice, Bcrp1$$^{-/-}$$ mice, and Mrp2$$^{-/-}$$ mice were 8.47, 3.79, and 5.18, respectively. The pharmacokinetic profiles after the i.v. injection (i.v.) of 2 mg/kg (10.41 μmol/kg) 4-ME are shown in Fig. 2. C and D, and the pharmacokinetic parameters are shown in Table 4. The AUC$$_{0-\infty}$$ values of 4-ME-G in Bcrp1$$^{-/-}$$ (162.83 ± 33.01 minutes • μmol/l) and Mrp2$$^{-/-}$$ mice (175.29 ± 33.66 minutes • μmol/l) were significantly higher than that in wild-type FVB mice (55.08 ± 13.80 minutes • μmol/l) ($P < 0.05$). The $$\%$$ of 4-ME in wild-type FVB mice, Bcrp1$$^{-/-}$$ mice, and Mrp2$$^{-/-}$$ mice were 22.28%, 45.70%, and 22.97%, respectively. The AUC$$_{0-\infty}$$ ratios of 4-ME-G to 4-ME (M/P AUC ratios) in wild-type FVB mice, Bcrp1$$^{-/-}$$ mice, and Mrp2$$^{-/-}$$ mice were 0.96, 1.92, and 1.95, respectively.

**Absorption and Metabolic Characteristics of ET and 4-ME in Caco-2 Monolayers.** Figure 3 shows the absorption and metabolic characteristics of ET and 4-ME in Caco-2 cells. The mean $$P_{app}$$ values of ET were significantly higher than those of 4-ME regardless of whether the transportation direction was from the AP side to basolateral side (AP-BL) or from the BL side to AP side (BL-AP) (Fig. 3A) ($P < 0.05$).

M/P AUC ratios, the AUC0−t ratio of ET to 4-ME; T1/2, half-life.

*p < 0.05 indicates a statistically significant difference between wild-type FVB mice and Bcrp1−/− mice.

The mean $P_{app}$ values of ET and 4-ME in AP-BL were $2.36 \times 10^{-5}$ and $0.59 \times 10^{-5}$ cm/s, respectively. The mean $P_{app}$ values of ET and 4-ME in BL-AP were $2.55 \times 10^{-5}$ and $0.69 \times 10^{-5}$ cm/s, respectively (Fig. 3A). In the transport experiment, 4-ME showed significantly larger metabolized fractions ($F_{met}$) than those of ET in AP-BL (0.11 for ET vs. 0.25 for 4-ME) and BL-AP (0.10 for ET vs. 0.27 for 4-ME) (Fig. 3B) ($P < 0.05$), and 4-ME yielded lower intracellular concentrations than ET in both AP-BL (0.039 mM for ET vs. 0.0048 mM for 4-ME) and BL-AP (0.042 mM for ET vs. 0.007 mM for 4-ME) (Fig. 3C). For the ET and 4-ME glucuronides in the transport experiment, 4-ME-G also produced lower intracellular concentrations than ET-G in both AP-BL (0.016 mM for ET-G vs. 0.0068 mM for 4-ME-G) and BL-AP (0.022 mM for ET-G vs. 0.0055 mM for 4-ME-G) (Fig. 3D) ($P < 0.05$). For the AP-BL transport experiment, the $J$ of 4-ME-G were 2.65- and 1.58-fold higher than those of ET-G on the BL and AP sides, respectively (Fig. 3E) ($P < 0.05$). For the BL-AP transport experiment, the $J$ of 4-ME-G were 2.58- and 1.82-fold higher than those of ET-G on the AP and BL sides, respectively (Fig. 3F) ($P < 0.05$). For the BL-AP transport experiment, the CL rates of 4-ME-G were 11.12- and 8.16-fold higher than those of ET-G on the AP and BL sides, respectively (Fig. 3H) ($P < 0.05$). For the AP-BL transport experiment, the CL rates of 4-ME-G were 11.12- and 8.16-fold higher than those of ET-G on the AP and BL sides, respectively (Fig. 3I) ($P < 0.05$). For the BL-AP transport experiment, the CL rates of 4-ME-G were 11.12- and 8.16-fold higher than those of ET-G on the AP and BL sides, respectively (Fig. 3H) ($P < 0.05$).

Effects of Inhibitors on the Glucuronidation Disposition of ET and 4-ME in Caco-2 Monolayers. The effects of Ko143 (BCRP inhibitor) and MK571 (MRPs inhibitor) on the glucuronidation disposition of ET and 4-ME are presented in Fig. 4. The excretion amounts of ET-G and 4-ME-G on the BL sides were 5- to 8-fold more, respectively, than those of ET-G and 4-ME-G on the AP side regardless of the side where the substrates were loaded. The excretion amounts of ET-G on both the AP and BL sides were significantly decreased in the presence of 5 μM Ko143 and 10 μM MK571 (Fig. 4, A–D). Similar results were observed in the excretion of 4-ME-G in the presence of 5 μM Ko143 and 10 μM MK571 (Fig. 4, E–H). The effects of Ko143 and MK571 on the $J$ and CL of glucuronides (ET-G and 4-ME-G) are shown in Fig. 5. Ko143 and MK571 significantly reduced the $J$ and CL values of ET-G in the bidirectional transport experiment (Fig. 5, A, B, E, and F) ($P < 0.05$). Unlike that of ET-G, Ko143 reduced the $J$ of 4-ME-G on both the AP and BL sides when 4-ME was loaded on the AP side (Fig. 5C) ($P < 0.05$), but
their $J$ and $CL$ values were not significantly inhibited by MK571 (Fig. 5, D, G, and H). The intracellular concentrations of ET-G were significantly decreased by Ko143 in the BL-AP transport experiment ($P < 0.05$), whereas the intracellular concentrations of 4-ME-G were not changed on both sides (Fig. 6, A and B). MK571 did not alter the intracellular concentrations of ET-G and 4-ME-G regardless of the side on which the ET (or 4-ME) was loaded. MK571 significantly decreased the $F_{net}$ of ET-G (Fig. 6C). Ko143 and MK571 did not influence the $F_{net}$ of 4-ME-G in the transport experiment (Fig. 6D).

**Glucuronidation Disposition of ET and 4-ME in Wild-Type, Bcrp1$^{-/-}$, and Mrp2$^{-/-}$ FVB Mice.** The perfused mouse model was used to further confirm the role of Bcrp1 and Mrp2 in the disposition of ET (Fig. 7) and 4-ME (Fig. 8). The $P_e$ values of ET (or 4-ME) and amount of ET (or 4-ME) absorbed and percentage of excreted ET-G (or 4-ME-G) in a 15-minute interval were determined and normalized over a 10-cm intestinal length. The exposure levels of ET-G (or 4-ME-G) in bile and plasma at the end of the perfusion were determined by the ratio value ($A_{ET\text{-}CL}$/AIS) of the peak area of ET-G to the peak area of IS (testosterone) (or $A_{4\text{-}ME\text{-}G}$/AIS). The $P_e$ values of ET in the upper small intestine (duodenum) ranged from $1.84 \pm 0.37$ without a significant difference among the three mouse genotypes (Fig. 7A). The $P_e$ values of ET in colon are significantly decreased from $5.99 \pm 0.75$ in wild-type FVB mice to $1.58 \pm 0.75$ and $1.42 \pm 0.88$ in Bcrp1$^{-/-}$ and Mrp2$^{-/-}$ mice, respectively (Fig. 7D).

The $P_e$ values of 4-ME in the upper small intestine (duodenum) ranged from $1.81 \pm 0.39$ to $2.54 \pm 0.52$ (Fig. 7A). A slight but significant increase was noted in the $P_e$ value in Bcrp1$^{-/-}$ mice compared with that in wild-type FVB mice (Fig. 8A) ($P < 0.05$). The duodenum and colon showed comparative $P_e$ values and absorbed amounts for 4-ME (Fig. 8, A and B). The duodenum excreted more 4-ME-G than the colon in perfusate (Fig. 8C). The 4-ME-G showed higher concentrations in both bile and plasma than 4-ME (Fig. 8, D and E). The concentrations of 4-ME-G (13.67 ± 10.10) were increased in the bile of Bcrp1$^{-/-}$ (7.48 ± 5.34) and Mrp2$^{-/-}$ (2.25 ± 1.72) mice compared with that in wild-type FVB mice, but the increase was not statistically significant.

$M/P$ AUC ratios, the $AUC_{0-\infty}$ ratio of 4-ME-G to 4-ME; $T_{1/2}$, half-life; $T_{max}$, time to reach maximum plasma concentration.

$*P < 0.05$ indicates a statistically significant difference between wild-type FVB mice and Bcrp1$^{-/-}$ mice (or Mrp2$^{-/-}$ mice).

**TABLE 3**

Pharmacokinetic parameters of 4-ME and 4-ME-G in wild-type, Bcrp1$^{-/-}$, and Mrp2$^{-/-}$ FVB mice after oral administration of 10 mg/kg (52.03 µmol/kg) 4-ME

**TABLE 4**

Pharmacokinetic parameters of 4-ME and 4-ME-G in wild-type, Bcrp1$^{-/-}$, and Mrp2$^{-/-}$ FVB mice after i.v. injection of 2 mg/kg (10.41 µmol/kg) 4-ME

Data are presented as means ± S.D. (n = 5); unpaired Student’s $t$ test was used to analyze the data.
Discussion

In our previous study, we had demonstrated that both ET and 4-ME were metabolized to 7-O-glucuronides (ET-G and 4-ME-G, respectively) in human liver and intestinal microsomes (Zhu et al., 2015). The metabolism studies in rats and mice also showed that the 7-C position glucuronidation reaction is the unique metabolic pathway for ET and 4-ME (unpublished data). The transportation of glucuronides depends mostly on the excretion of transporters that are commonly located on the AP and BL membranes of many cells. Thus, in the current study, transporter knockout mice and Caco-2 cells were employed to explore the role of BCRP and MRP2 in the disposition of ET-G and 4-ME-G in vitro and in vivo.

The pharmacokinetic study and perfusion experiment in knockout mice and inhibition assays in Caco-2 monolayers provided considerable evidence supporting the important role of BCRP and MRP2 in the excretion of ET-G and 4-ME-G. The pharmacokinetic data showed that

Fig. 3. Absorption and metabolic characteristics of ET and 4-ME in Caco-2 monolayers. ET or 4-ME (10 μM) was loaded onto the AP side (AP-BL) or BL side (BL-AP) of Caco-2 monolayers. At 0.5, 1, 1.5, and 2 hours, three samples (500 μl) from both sides of each Transwell were collected and determined. (A) $P_{app}$ of ET and 4-ME; (B) metabolism fraction ($F_{met}$) of ET and 4-ME; (C) intracellular ET and 4-ME concentrations; (D) intracellular ET-G and 4-ME-G concentrations; (E) $J$ of ET-G and 4-ME-G from the intracellular to the BL side (AP-BL); (F) $J$ of ET-G and 4-ME-G from the intracellular to the AP side (BL-AP); (G) $CL$ of ET-G and 4-ME-G from the intracellular to the BL side (AP-BL); and (H) $CL$ of ET-G and 4-ME-G from the intracellular to the AP side (BL-AP).
ET and 4-ME are mainly present as ET-G and 4-ME-G in plasma (Figs. 1 and 2). This result was consistent with our previous study showing that ET and 4-ME easily undergo 7-O glucuronidation metabolism by human hepatic and intestinal microsomes (Zhu et al., 2015). The pharmacokinetic parameters of ET-G and 4-ME-G in knockout mice exhibited significant differences from those in wild-type FVB mice (Tables 1–4).

Fig. 4. Effects of Ko143 (inhibitor of BCRP) and MK571 (inhibitor of MRP2) on the excretion amounts of ET-G (A–D) and 4-ME-G (E–H) from the cellular membrane to the AP and BL sides. The experiment was set up as follows: ET or 4-ME (10 μM) was loaded on the AP or BL side; Ko143 (5 μM) or MK571 (10 μM) was loaded on the AP side; or no inhibitor was added as the control group. The amounts of ET-G or 4-ME-G on the AP or BL side were determined at 0.5, 1, 1.5, and 2 hours after incubation. The data points represent the average values of the triplicate samples, and the error bars represent the S.D. of the mean. Unpaired Student’s t test was used to analyze the data. The asterisk (*) indicates a statistically significant difference between the control and inhibited groups at \( P < 0.05 \).
The AUC\textsubscript{0}\textsuperscript{-}\textsuperscript{t} values of ET and 4-ME, and their glucuronides (ET-G and 4-ME-G), were significantly increased in most of Bcrp1\textsuperscript{2/2} and Mrp2\textsuperscript{2/2} mice compared with those in wild-type FVB mice after oral or i.v. administration of ET or 4-ME. The average absolute $F$ of ET or 4-ME were increased in Bcrp1\textsuperscript{2/2} mice (17.10\% for ET and 45.70\% for 4-ME) compared with those in wild-type FVB mice (10.07\% for ET or 4-ME).
and 22.28% for 4-ME) (Tables 2–4). These results suggested that Bcrp1 and Mrp2 might be involved in the disposition of ET-G and 4-ME-G. The inhibition assays in Caco-2 cells were conducted to verify the role of BCRP and MRP2 on the disposition of ET-G and 4-ME-G in vitro. In the inhibition assays in Caco-2 monolayers, the excretion of ET-G and 4-ME-G was significantly inhibited in the presence of the Ko143 (BCRP inhibitor) or MK571 (MRP2 inhibitor) on the AP side of Caco-2 monolayers (Fig. 4). The $J$ and $CL$ of ET-G and 4-ME-G were also significantly decreased by Ko143 and MK571 (Fig. 5). These results also suggested that BCRP and MRP2 are probably involved in excreting ET-G and 4-ME-G. Additionally, the perfusion experiment in transporter knockout mice showed that Bcrp1 deficiency significantly

**Fig. 6.** Effect of Ko143 and MK57 on the intracellular concentrations of ET-G (A) and 4-ME-G (B), and metabolism fraction ($F_{\text{met}}$) of ET (C) and 4-ME (D) on both the AP side to BL side (AP-BL) and BL side to AP side (BL-AP) in Caco-2 monolayers. The experiment was set up as follows: 10 μM ET or 4-ME was loaded on the AP or BL side; Ko143 (5 μM) or MK571 (10 μM) was loaded on the AP side; or no inhibitor was added as the control group. The amounts of ET-G and 4-ME-G on the AP and BL sides as well as their intracellular concentrations were determined at 0.5, 1, 1.5, and 2 hours after incubation. $F_{\text{met}}$ was determined by comparing the total amounts of glucuronides and the parent compound. The data points represent the average values of the triplicate samples, and the error bars represent the S.D. of the mean. Unpaired Student’s $t$ test was used to analyze the data. The asterisk (*) indicates a statistically significant difference between the control and inhibited groups at $P < 0.05$.

**Fig. 7.** Effective intestinal permeability as well as the absorption and metabolism of ET in the mouse intestinal perfusion model. Two segments (upper small intestine and colon) were perfused simultaneously at a flow rate of 0.167 ml/min using concentration of 70 μM ET. The $P_{\text{eff}}$ of ET (A), amount of ET absorbed (B), and percentage of excreted ET-G (C) in a 15-minute interval were determined and normalized over a 10-cm intestinal length. The exposure levels of ET-G in bile (D) and plasma (E) at the end of the perfusion were determined by the ratio of the peak area of ET-G to that of the IS. Each column represents the average of the determinations, and the error bar represents the S.D. of the mean (the number of mice in each group ranged from 3 to 5). Unpaired Student’s $t$ test was used to analyze the data. The asterisk (*) indicates a statistically significant difference between wild-type FVB mice and knockout mice at $P < 0.05$.

In conclusion, this work revealed that both BCRP and MRP2 are involved in the disposition of ET-G and 4-ME-G because MK571 is not a specific inhibitor of MRP2 (Gao et al., 2018). In the inhibition assays in Caco-2 monolayers, the excretion of ET-G in the Bcrp1−/− and Mrp2−/− mice were markedly decreased compared with that in wild-type FVB mice, but the effect was not statistically significant (Fig. 7D). The lack of significance of these data can be explained by the large derivation. However, these results also suggested that Mrp2 is probably involved in the ET-G excretion. No significant decrease was observed for 4-ME-G intestinal and bile excretions in Bcrp1- or Mrp2-deficient mice, implying that Mrp2 compensated the functional Bcrp1 when there was a BCRP deficiency, and vice versa (Fig. 8, C and D). These results suggested that both Bcrp1 and Mrp2 had a comparable capacity in excreting 4-ME-G into the intestine and bile. 

Other MRPs, including MRP3 and MRP4, that are expressed on the BL membrane of the Caco-2 cells also might be involved in the excretion of ET-G and 4-ME-G because MK571 is not a specific inhibitor of MRP2 (Gao et al., 2018). In the inhibition assays in Caco-2 monolayers, the excretion of ET-G and 4-ME-G was inhibited by MK571, which was loaded on the AP side (Fig. 4). Furthermore, MK571 showed a stronger inhibition effect on the excretion of ET-G and 4-ME-G than Ko143. These results are probably due to two reasons. First, no BCRP was loaded on the AP side (Fig. 4). Furthermore, MK571 showed a stronger inhibition effect on the excretion of ET-G and 4-ME-G than Ko143. These results suggested that the extensive glucuronidation of ET and 4-ME resulted in their poor diffusion in Caco-2 cells (Fig. 3A). Meanwhile, the Papp*eff values of ET and 4-ME were close to 2 (or were greater than 2) in the duodenum in the perfusion experiment, also suggesting that ET and 4-ME possess a good permeability (Fig. 7A; Fig. 8A). However, the F% values of ET and 4-ME in wild-type FVB mice were 10.07% and 22.28%, respectively. These results suggested that the extensive glucuronidation of ET and 4-ME resulted in their poor F%. The 4-ME-G yielded higher metabolism fractions (Fmet), J, and CL than ET-G yielded, and 4-ME-G showed lower intracellular concentrations in the absence or presence of chemical inhibitors (Figs. 3–6). These results implied that 4-ME may be more rapidly metabolized than ET in vivo.

In conclusion, this work revealed that both BCRP and MRP2 are involved in the disposition of ET-G and 4-ME-G. Compared with MRP2, BCRP exhibited a predominant transport capacity in excreting ET-G into the intestine and bile.

---

**Fig. 8.** Effective intestinal permeability as well as absorption and metabolism of 4-ME in a mouse intestinal perfusion model. Two segments (upper small intestine and colon) were perfused simultaneously at a flow rate of 0.167 ml/min using concentration of 70 μM 4-ME. The Papp*eff of 4-ME (A), amount of 4-ME absorbed (B), and percentage of excreted 4-ME-G (C) in a 15-minute interval were determined and normalized over a 10-cm intestinal length. The exposure levels of 4-ME-G in bile (D) and plasma (E) at the end of the perfusion were determined by the ratio of the peak area of 4-ME-G to that of the IS. Each column represents the average of determinations, and the error bar represents the S.D. of the mean (the number of mice in each group ranged from three to five). Unpaired Student’s t test was used to analyze the data. The asterisk (*) indicates a statistically significant difference between wild-type FVB mice and knockout mice at P < 0.05.
the intestinal lumen. ET and ME-4 are most likely absorbed via passive diffusion, and the extensive glucuronidation resulted in their poor Frr.
