Received April 10, 2020; accepted June 1, 2020

ABSTRACT

Cannabis is used for both recreational and medicinal purposes. The most abundant constituents are the cannabinoids - cannabidiol (CBD, nonpsychoactive) and (−)-trans-Δ9-tetrahydrocannabinol (THC, psychoactive). Both have been reported to reversibly inhibit or inactivate cytochrome P450 (CYPs) enzymes. However, the low aqueous solubility, microsomal protein binding, and nonspecific binding to labware were not considered, potentially leading to an underestimation of CYPs inhibition potency. Therefore, the binding-corrected reversible (IC50,u) and irreversible (Ki,u) inhibition potency of each cannabinoid toward major CYPs were determined. The fraction unbound of CBD and THC in the incubation mixture was 0.12 ± 0.02, respectively. The IC50,u for CBD toward CYP1A2, 2C9, 2C19, 2D6, and 3A was 0.45 ± 0.17, 0.17 ± 0.03, 0.30 ± 0.06, 0.95 ± 0.50, and 0.38 ± 0.11 μM, respectively; the IC50,u for THC was 0.05 ± 0.02, 0.012 ± 0.001, 0.57 ± 0.22, 1.28 ± 0.25, and 1.30 ± 0.34 μM, respectively. Only CBD showed time-dependent inactivation (TDI) of CYP1A2, 2C19, and 3P3A, with inactivation efficiencies (knoa/kiu) of 0.70 ± 0.34, 0.11 ± 0.06, and 0.14 ± 0.04 minutes−1 μM−1, respectively. A combined (reversible inhibition and TDI) mechanistic static model populated with these data predicted a moderate to strong pharmacokinetic interaction risk between orally administered CBD and drugs extensively metabolized by CYP1A2/2C9/2C19/2D6/3A and between orally administered THC and drugs extensively metabolized by CYP1A2/2C9/3A. These predictions will be extended to a dynamic model using physiologically based pharmacokinetic modeling and simulation and verified with a well-designed clinical cannabidiol-drug interaction study.

SIGNIFICANCE STATEMENT

This study is the first to consider the impact of limited aqueous solubility, nonspecific binding to labware, or extensive binding to incubation protein shown by cannabidiol (CBD) and delta-9-tetrahydrocannabinol (THC) on their true cytochrome P450 inhibitory potency. A combined mechanistic static model predicted a moderate to strong pharmacokinetic interaction risk between orally administered CBD and drugs extensively metabolized by CYP1A2, 2C9, 2C19, 2D6, or 3A and between orally administered THC and drugs extensively metabolized by CYP1A2, 2C9, or 3A.

Introduction

Cannabis (also known as marijuana) is the most commonly used recreational illicit substance in the United States, with an estimated 22.2 million users ((Bose et al., 2016). Cannabis and its main phytoconstituents, cannabinoids, are also used to treat a variety of ailments, including pain, nausea, loss of appetite, and childhood epilepsy (Grotenhermen, 2003; Cox et al., 2019). To date, cannabis has been legalized in 33 states, including the District of Columbia, for medicinal use and in 11 states for recreational use (https://www.ncsl.org/research/health/state-medical-marijuana-laws.aspx). Among users in the United States, 53% consume cannabis for recreational purposes, 11% for medicinal purposes, and 36% for both recreational and medicinal purposes (Schauer et al., 2016). Because of the ever-increasing use of cannabis, especially in populations taking multiple medications, determining potential pharmacokinetic interactions between cannabinoids and coadministered medications is imperative.

The prevalent cannabinoids in cannabis products include the nonpsychoactive constituent, cannabidiol (CBD), and the psychoactive constituent, (−)-trans-Δ9-tetrahydrocannabinol (THC) (Fig. 1). CBD...
and THC have been shown to reversibly inhibit cytochrome P450 (CYP) 1A1, 1B1, 2A6, 2B6, 2D6, 2J2, and 3A with varying degrees of potency; IC_{50} or K_{i} values ranged from 0.20 to 36 μM (Yamaori et al., 2010; Arnold et al., 2018; Cox et al., 2019). In addition, CBD showed time-dependent inactivation (TDI) of CYP1A1, 1A2, and 1B1, whereas THC showed TDI of CYP1A1 and 2A6 (Yamaori et al., 2010, 2011b). However, the inhibition potency of these cannabinoids was likely underestimated because their poor aqueous solubility and extensive binding to microsomal proteins and labware (Garrett and Hunt, 1974) were not considered.

THC is metabolized to an active metabolite, 11-hydroxy-THC (11-OH-THC), which is further metabolized to the inactive metabolite, 11-nor-9-carboxy-Δ^2-THC (COOH-THC) (Fig. 1). These metabolites have been detected in the systemic circulation at higher concentrations than THC after oral administration of THC (Frytak et al., 1984; Nadulski et al., 2005). Consequently, these metabolites should be considered when predicting the magnitude of a THC-mediated drug interaction as recommended by the US Food and Drug Administration (FDA) (https://www.fda.gov/media/134582/download). However, the potential for 11-OH-THC/COOH-THC to inhibit CYPs has not been previously determined.

Based on these knowledge gaps, the objective of this study was to predict the potential for CBD and THC to precipitate CYP-mediated pharmacokinetic drug interactions in vivo. The aims were to: 1) determine the average oral or inhalational doses of CBD and THC used for recreational or medicinal purposes, allowing estimation of the maximum plasma concentration of CBD and THC (and circulating cannabinoid. Both CBD and THC were predicted to precipitate pharmacokinetic interactions with several of the probe drugs after oral administration, warranting further investigation via physiologically based pharmacokinetic (PBPK) modeling and simulation and, potentially, clinical evaluation.

**Materials and Methods**

**Biologic Materials, Chemicals, and Reagents**

Pooled adult human liver microsomes (HLMs) (mixed gender; pool of 50 donors) were purchased from Corning Inc. (Corning, NY). Drug Enforcement Administration–exempt methanolic stock solutions of (-)-Δ9-THC (1 mg/ml), (±)-11-OH-THC (0.1 mg/ml), and (±)-COOH-THC (0.1 mg/ml) as well as tolbutamide were purchased from Cerilliant (Round Rock, TX). (-)-Δ9-THC, CBD, omeprazole, testosterone, dextromethorphan, phenacetin, diclofenac, 5-hydroxy omeprazole, 6β-hydroxy testosterone, dextrophan, acetaminophen, and 4-hydroxy diclofenac were purchased from Cayman Chemicals (Ann Arbor, MI). Micro ultracentrifuge polycarbonate tubes and Dulbecco’s phosphate-buffered saline were purchased from Thermo Scientific (Avenue, NC). Ultralow-binding microcentrifuge tubes, bovine serum albumin (BSA), acetonitrile, and formic acid were purchased from Fisher Scientific (Hamilton, NY). β-nicotinamide adenine dinucleotide phosphate (NADP+), D-glucose 6-phosphate (G6P), and glucose-6-phosphate dehydrogenase were purchased from Sigma-Aldrich (St. Louis, MO). Milli-Q water was used for all preparations. All other chemicals and experimental reagents were obtained from reputable commercial sources.

**Search Strategy to Determine Oral or Inhalational Doses of CBD and THC Used for Recreational and/or Medicinal Purposes**

To predict the magnitude of pharmacokinetic CBD- or THC-drug interactions, the average and maximum oral and/or inhalational doses of each cannabinoid used for recreational and/or medicinal purposes is required. Epidiolex (CBD) and Marinol (THC) are FDA-approved drugs indicated for childhood epileptic seizures and chemotheraphy-induced nausea, respectively. In addition, numerous clinical trials involving CBD and THC have been conducted to determine their efficacy for various medicinal purposes. FDA-recommended CBD and THC doses and their average doses used in clinical trials and case reports were collected and tabulated (Supplemental Tables 1 and 2). To estimate the average THC and CBD doses for recreational and/or medicinal use, a thorough search of the doses reported in social media, cannabinoid vendor websites, and newspapers was conducted. The doses were categorized as either low (CBD ≤ 200 mg or THC ≤ 50 mg) or high (CBD > 200 mg or THC > 50 mg) (Supplemental Tables 1 and 2). The cutoffs were based on natural clustering. Average low and high doses of CBD or THC were calculated. The maximum dose of CBD or THC for recreational and/or medicinal use was tabulated (Supplemental Tables 1 and 2).

**Cannabinoid Biorelevant Solubility**

**Preparation of FaSSIF-v2 and FeSSIF-v2 Media.** FaSSIF-v2 (fused state simulated intestinal fluid v2) and FeSSIF-v2 (fed state simulated intestinal fluid v2) media were prepared fresh on the day of an experiment according to the manufacturer’s protocol (https://biorelevant.com/fassif-fassif-fassgf/buy/). A blank buffer (50 ml) for FaSSIF-v2 composed of sodium hydroxide (0.07 g), maleic acid (0.11 g), and sodium chloride (0.20 g) was prepared, and the pH was adjusted to 6.5 with sodium hydroxide (1 N). FaSSIF powder (0.09 g) was added to 25 ml of blank buffer. A similar procedure was used for FeSSIF-v2 of which a blank buffer composed of sodium hydroxide (0.16 g), maleic acid (0.32 g), and sodium chloride (0.37 g) was adjusted to pH 5.8 with sodium hydroxide (1 N). FeSSIF-v2 powder (0.49 g) was added to 25 ml of blank buffer. Both FaSSIF and FeSSIF solutions were stirred to dissolve the powder. The volume of each solution was increased to 50 ml using respective blank buffer. The solutions were allowed to stand at room temperature for 1 hour prior to experimentation.

**Determination of Cannabinoid Solubility.** The maximum gastrointestinal solubility of CBD and THC was determined using FaSSIF-v2 or FeSSIF-v2.
medium (prepared as described above). Aliquots from CBD or THC stock solutions in methanol (1 mg/ml) were added to FaSSIF-v2 or FeSSIF-v2 medium in low-binding microcentrifuge tubes to achieve a maximum concentration of 100 μM. The tubes were incubated in an air incubator maintained at 37°C with continuous shaking and protected from light. The incubation was carried out for 24 hours to achieve a presumptive thermodynamic equilibrium. At the end of the incubation, the tubes were centrifuged at 15,000g for 5 minutes at 4°C. The supernatant was subjected to liquid chromatography–tandem mass spectrometry (LC-MS/MS) analysis (described below).

**Reversible CYP Inhibition by Cannabinoids**

Because THC exhibits low aqueous solubility (2.8 μg/ml) and extensive binding (70%–97%) to protein and labware (Garrett and Hunt, 1974), microsomal incubation conditions were optimized to prevent underestimation of inhibitory potency (IC50 or KI). To reduce nonspecific binding and adsorption to labware, low-binding microcentrifuge tubes were used, and BSA (0.2%) was included in the incubation mixtures. The latter also served to increase cannabinoid solubility.

A previously validated CYP cocktail assay was modified to simultaneously evaluate inhibition of CYP1A2, 2C9, 2C19, 2D6, and 3A by each cannabinoid (Dixit et al., 2007; Dingert et al., 2014; Chen et al., 2016). The cocktail consisted of the probe substrates phenacetin (CYP1A2; 50 μM), dicyclofenac (CYP2C9; 5 μM), omeprazole (CYP2C19; 10 μM), dextromethorphan (CYP2D6; 5 μM), and testosterone (CYP3A; 10 μM) at concentrations less than reported KI values (Spaggiari et al., 2014; Dahlinger et al., 2016). The cocktail was optimized for linearity of metabolite formation with respect to time and microsomal protein concentration. The probe substrates showed minimal interaction with each other (data not shown).

To determine the inhibitory effects of each cannabinoid on CYP activity, reaction mixtures (200 μl) were prepared in low-binding Eppendorf tubes that consisted of HLMs (0.1 mg/ml), CYP cocktail, and THC (0.003 M), 11-OH-THC (0.1–50 μM), or COOH-THC (0.1–50 μM) in 0.1 M potassium phosphate buffer (pH 7.4) containing 0.2% BSA. Stock solutions of probe substrates were prepared in DMSO. The final concentration of DMSO was 0.4% in each incubation mixture. Mixtures were equilibrated for 10 minutes (0.003 M), 11-OH-THC (0.1–50 μM), or COOH-THC (0.1–50 μM) at concentrations less than reported KI values (Spaggiari et al., 2014; Dahlinger et al., 2016). The cocktail was optimized for linearity of metabolite formation with respect to time and microsomal protein concentration. The probe substrates showed minimal interaction with each other (data not shown).

To determine the inhibitory effects of each cannabinoid on CYP activity, reaction mixtures (200 μl) were prepared in low-binding Eppendorf tubes that consisted of HLMs (0.1 mg/ml), CYP cocktail, and THC (0.003–100 μM), CBD (0.003–100 μM), 11-OH-THC (0.1–50 μM), or COOH-THC (0.1–50 μM) in 0.1 M potassium phosphate buffer (pH 7.4) containing 0.2% BSA. Stock solutions of probe substrates were prepared in DMSO. The final concentration of DMSO was 0.4% in each incubation mixture. Mixtures were equilibrated for 10 minutes at 37°C in a heating block with constant stirring (300 rpm). After 10 minutes, the NADPH regenerating system (1.3 M NADP+, 3.3 M g/ml G6P, 3.3 M MgCl2, and 0.4 U/ml G6P dehydrogenase) was added to initiate the reaction. After an additional 10 minutes (with THC) or 15 minutes (with CBD, 11-OH-THC, or COOH-THC), reactions were quenched with 200 μl ice-cold acetonitrile containing internal standard (125 nM tolbutamide). Reaction mixtures were processed and analyzed as described for reversible inhibition experiments. Three or four independent experiments were conducted, each in duplicate.

The observed first-order rate constants for inactivation (kinc) were calculated as described previously (Cheong et al., 2017). The maximal inactivation rate constant (kinc, max) and half-maximal inactivation concentration (K1/2) were estimated by nonlinear least-squares regression analysis (GraphPad Prism 6.01; Graphpad Software Inc., San Diego, CA) of the kobs versus inactivator concentration ([I]) data using the following equation:

\[
\text{k}_{\text{obs}} = \frac{k_{\text{max}} \times [I]}{K_1 + [I]}
\]

**Cannabinoid Protein Binding in Incubation Mixture**

Cannabinoid binding to proteins in the incubation mixture (fproteins) was determined using the tube adsorption method (Patilea-Vrana and Unadkat, 2019). In brief, HLMs (0.1 mg/ml) were incubated with BSA (0.2%) and CBD (0.1 and 5 μM) for 10 minutes or THC (0.5 and 5 μM) or 11-OH-THC (0.1 μM) for 15 minutes. Three independent experiments were conducted, each in quadruplicate. Microsomal protein concentrations in the incubation mixtures for inactivation experiments (0.5 mg/ml) were five-times greater than that used for reversible inhibition experiments (0.1 mg/ml); BSA concentration (0.2%) was same in both experiments. As we previously reported, binding to incubation proteins is predominated to BSA, not to microsomal protein (Patilea-Vrana and Unadkat, 2019). Therefore, the fproteins of CBD or THC, assumed to be independent of the HLMs, was used to compute the binding-corrected IC50 and KI values.

**LC-MS/MS Analysis**

Acetaminophen, 4-hydroxy diclofenac, 5-hydroxy omeprazole, dextromethorphan, 6β-hydroxy testosterone, and tolbutamide were quantified using an ACQUITY ultra-high-performance LC (UPLC) system (Waters, Milford, MA) coupled to an SCIEX 6500 QTRAP mass spectrometer (SCIEX, Framingham, MA). Chromatographic separation was achieved on an ACQUITY UPLC BEH C18 column (2.1 × 50 mm, 1.7 μm) with an ACQUITY UPLC BEH C18 VanGuard precolumn (2.1 × 5 mm, 1.7 μm). The column and the autosampler compartment were maintained at 45 and 4°C, respectively. The flow rate was 0.5 ml/min, and the sample injection volume was 10 μl. The mobile phases were water containing 0.1% formic acid (A) and acetonitrile containing 0.1% formic acid (B). The gradient conditions were optimized as follows: 5% B at 0.0 to 1.0 minute, linear increase from 5% to 95% B at 1.0 to 2.0 minutes, 95% B at 2.0–2.5 minutes, linear decrease from 95% to 5% B at 2.5–2.6 minutes, and 5% B at 2.6–3.2 minutes. The total run time was 3.2 minutes.

The mass spectrometer was operated in the positive electrospray ionization mode. Compound-dependent mass spectrometric parameters were optimized to achieve maximal ion intensities in the multiple reaction monitoring mode. Acetaminophen, 4-hydroxy diclofenac, 5-hydroxy omeprazole, dextromethorphan, 6β-hydroxy testosterone, and tolbutamide were quantified in the multiple reaction monitoring mode using the mass transition of m/z 152.0 → 110.0, 312.0 → 231.0, 362.0 → 214.0, 258.1 → 157.0, 305.3 → 269.1, and 271.3 → 155.0, respectively. The ion source parameters were as follows: spray voltage, 5500 V; ion source temperature, 600°C; curtain gas, 30 psi; ion source gas 1, 50 psi; and ion source gas 2, 50 psi.

CBD, THC, and THC metabolites were quantified using LC-MS/MS method as reported previously (Patilea-Vrana and Unadkat, 2019).

**Prediction of Cannabinoids to Precipitate Pharmacokinetic Drug Interactions**

Reversible inhibition (IC50,u) and inactivation parameters (KIC50,u and kinc) were calculated as described previously (Cheong et al., 2017) using in vitro methods similar to those described above. The predicted KIC50,u and kinc values were used to evaluate the potential of each cannabinoid to precipitate pharmacokinetic drug interactions.
TABLE 1

Oral and inhalational doses and estimated maximum plasma concentrations of CBD, THC, and THC metabolites used for predicting the magnitude of pharmacokinetic cannabinoid-drug interactions.

| Cannabinoid | CBD or THC Dose (mg) | Route of Administration | \(|I_{\text{uconc}}| (\text{nmol/L})^a| | \(|I_{\text{inlet,conc}}| (\mu \text{M})^a|
|---|---|---|---|---|
| CBD | 70 | Oral | 2.94 | 0.12 |
| | 700 | Oral | 29.4 | 1.24 |
| | 2000 | Oral | 84.0 | 3.55 |
| THC | 20 | Oral | 0.33 | 0.01 |
| | 130 | Oral | 2.15 | 0.03 |
| | 160 | Oral | 2.64 | 0.04 |
| | 25 | Inhalation | 2.72 | NA |
| | 70 | Inhalation | 7.62 | NA |
| | 100 | Inhalation | 10.89 | NA |
| 11-OH-THC | 20 | Oral | 0.26 | – |
| | 130 | Oral | 1.72 | – |
| | 160 | Oral | 2.11 | – |
| | 25 | Inhalation | 0.20 | NA |
| | 70 | Inhalation | 0.55 | NA |
| | 100 | Inhalation | 0.78 | NA |
| COOH-THC | 20 | Oral | 3.19 | – |
| | 130 | Oral | 20.75 | – |
| | 160 | Oral | 25.54 | – |
| | 25 | Inhalation | 1.12 | NA |
| | 70 | Inhalation | 3.13 | NA |
| | 100 | Inhalation | 4.48 | NA |

| \(k_{\text{deg,H}}\) (CBD) | 0.007 (Taylor et al., 2019) |
| \(k_{\text{deg,H}}\) (THC) | 0.011 (Patilea-Vrana and Unadkat, 2019) |
| \(f_{\text{inlet}}\) (11-OH-THC) | 0.012 (Patilea-Vrana and Unadkat, 2019) |
| \(k_{\text{inact}}\) (COOH-THC) | not available |
| \(v_{\text{inlet}}\) (CBD and THC) | 1 (estimated based on FDA guidance) |
| \(v_{\text{inlet}}\) (CBD) | 0.048 min\(^{-1}\) (estimated from Epidiolex (CBD) pharmacokinetic data using Phoenix WinNonlin (Phoenix WinNonlin 8.1; Certara USA, Princeton, NJ)) |
| \(Q_{\text{hpf}}\) (hepatic blood flow) | 1500 ml/min |
| \(R_{\text{G}}\) (THC) (blood to plasma ratio) | 0.4 (Schwikel et al., 2009) |

\(NA, \text{not applicable; } \sim, \text{not estimated as data on fraction of dose metabolized to these metabolites by the intestine vs. liver are not available.}\)

\(AUC_{\text{R}} = \frac{AUC_{\text{RO}}}{AUC_{\text{C2}}} = \left[\frac{1}{A \times B \times f_{\text{a}} + (1 - f_{\text{a}})}\right] \times \frac{1}{X \times Y \times (1 - F_{\text{a}}) + F_{\text{a}}} \) (1)

A is the term that describes TDI of a CYP enzyme observed in the liver:

\(A = \frac{k_{\text{deg,H}}}{k_{\text{deg,H}} + \frac{f_{\text{inlet}}}{f_{\text{inlet}} + k_{\text{deg,H}}}} \) (2)

B is the term that describes reversible inhibition of a CYP enzyme observed in the liver:

\(B = \frac{1}{1 + \frac{f_{\text{a}}}{f_{\text{a}}}} \) (3)

X is the term that describes TDI of a CYP enzyme observed in the intestine:

\(X = \frac{k_{\text{deg,G}}}{k_{\text{deg,G}} + \frac{f_{\text{inlet}}}{f_{\text{inlet}} + k_{\text{deg,G}}}} \) (4)

Y is the term that describes reversible inhibition of a CYP enzyme observed in the intestine:

\(Y = \frac{1}{1 + \frac{f_{\text{a}}}{f_{\text{a}}}} \) (5)

and \(|I_{\text{u}}|\) is the unbound in vivo maximum plasma concentration of an inhibitor/inactivator in the liver. \(|I_{\text{u}}|\) is the in vivo concentration of an inactivator/inhibitor available to the enzyme in the intestine. \(k_{\text{deg,H}}\) and \(k_{\text{deg,G}}\) are the degradation rate constants of the CYP in the liver and intestine, respectively. \(f_{\text{a}}\) is the fraction of the object drug metabolized by a given CYP, and \(F_{\text{a}}\) is the fraction of the object drug escaping intestinal metabolism.

Each CYP probe drug except phenacetin and testosterone was used to predict the magnitude of the various potential CYP-mediated drug interactions in the liver or intestine precipitated by orally administered or inhaled CBD or THC. Because phenacetin is not used clinically and testosterone is an endogenous steroid hormone, theophylline and midazolam, respectively, were used as the object drugs to predict the magnitude of CYP1A2 and 3A4-mediated drug interactions. The \(f_{\text{u}}\) and \(F_{\text{C}}\) values of object drugs and \(k_{\text{deg}}\) value of CYP enzymes are given in Supplemental Table 1.

The maximum magnitude of a cannabinoid-drug interaction in the liver after oral cannabinoid administration was predicted using the following two different approaches: 1) unbound in vivo maximum plasma concentration of inhibitor/inactivator in hepatic portal vein (\(|I_{\text{uconc,conc}}|\) was set equal to \(|I_{\text{u}}|\) in eqs. 2 and 3 to predict interactions precipitated by inactivator/inhibitor, and 2) unbound in vivo maximum plasma concentration of inhibitor/inactivator (\(|I_{\text{inlet,conc}}|\) was set equal to \(|I_{\text{u}}|\) in eqs. 2 and 3 to predict interactions precipitated by inactivator (term A) and reversible inhibitor (term B), respectively. To predict the potential of orally administered CBD or THC to precipitate CYP2C9- and 3A4-mediated interactions in the intestine, the calculated maximum intestinal fluid solubility of CBD or THC was set equal to \(|I_{\text{u}}|\) in eqs. 4 and 5. To predict drug interactions precipitated by 11-OH-THC and COOH-THC, the \(|I_{\text{inlet,conc}}|\) of each metabolite was set equal to \(|I_{\text{u}}|\). To predict drug interactions precipitated by THC after inhalation, \(|I_{\text{inlet,conc}}|\) was set equal to \(|I_{\text{u}}|\) in eqs. 2 and 3.

The orally administered CBD doses used to predict in vivo hepatic and intestinal cannabinoid-mediated drug interactions were 70 mg (average low dose), 700 mg (average high dose), and 2000 mg (maximum dose used in the clinical studies) (Supplemental Table 1). For THC, oral doses of 20 mg (average low dose), 130 mg (average high dose), and 160 mg (maximum dose used in a clinical study) were used (Supplemental Table 2). The inhaled doses of THC were 25 mg (average low dose), 70 mg (average high dose), and 100 mg (maximum dose consumed for recreational use).

Results

Average and Maximum Doses and Plasma Concentrations of CBD and THC after Oral or Inhalational Administration when Used for Recreational or Medicinal Purposes. The recommended dose of Epidiolex (CBD) is 2.5–10 mg/kg twice daily (https://www.accessdata.fda.gov/drugsatfda_docs/label/2018/210365lbl.pdf). However, in clinical trials, CBD has been tested at 0.5–25 mg/kg twice daily, with an average oral dose of 7.5 mg/kg/twice daily, the equivalent of 600 mg twice daily for an average adult weighing 80 kg (Millar et al., 2019). In contrast, over-the-counter CBD products are used at much lower oral doses depending on the medical condition, including sleep disorders (20–80 mg twice daily), chronic pain (1.25–10 mg twice daily), movement problems (350 mg twice daily), schizophrenia (20–640 mg twice daily), and glaucoma (20–40 mg twice daily) (https://cbdsoilreview.org/cbd-cannabidiol/cbd-dosage). These products are commonly available in 1000–10,000 mg packs of 30–300 mg CBD per dose (https://www.amazon.com/Pack-10000mg-Hemp-Relief-Stress/dp/B07VL3B6MG). Despite that CBD has a long terminal half-life (56–61 hours), minimal drug accumulation is reported following multiple doses (https://www.accessdata.fda.gov/drugsatfda_docs/nda/2018/210365Orig1s000ClinPharmR.pdf). Therefore, single doses of CBD were used to predict the magnitude of oral CBD-drug interactions instead of multiple daily doses. Low and high single oral doses of CBD averaged 70 and 700 mg, respectively (Supplemental Table 2). A maximum CBD dose of 2000 mg used in previous clinical studies was also tested (Devinsky et al., 2016; Hess et al., 2016; Rosenberg et al., 2017; Warren et al., 2017).

THC is consumed orally at doses of 1–2.5 mg (by inexperienced users) and 50–100 mg (by experienced users) for both recreational and medicinal purposes (https://www.leafly.com/news/cannabis-101/cannabis-edibles-dosage-guide-chart). In clinical studies, THC has been administered orally at doses ranging from 8 to 156 mg. The
recommended dose of prescription THC (Marinol) is 10 mg twice daily. Based on these data, low and high single oral THC doses averaged 20 and 130 mg, respectively (Supplemental Table 3). The maximum oral dose of THC consumed for recreational or medicinal use was approximately 160 mg (Ware et al., 2015) and was used to predict the magnitude of oral THC-drug interactions.

THC is used recreationally at approximately 30–100 mg per joint, bong, or vaporizer (https://www.latimes.com/projects/la-me-weed-101-thc-calculator/), whereas the inhaled dose for medicinal use is lower at approximately 6–80 mg (Kahan et al., 2014; Ware et al., 2015). Based on these data, low and high single inhaled doses of THC averaged 25 and 70 mg, respectively (Supplemental Table 3). The maximum inhaled dose of THC was 100 mg (https://www.leafly.com/news/cannabis-101/cannabis-edibles-dosage-guide-chart) and was used to predict the magnitude of THC-drug interactions.

Based on the dose-normalized $C_{\text{max}}$ of CBD, THC, 11-OH-THC, and COOH-THC for various routes of administration of CBD and THC and their fraction unbound in plasma ($f_u,p$) (Cox et al., 2019), [$I_{\text{nax}}$] of CBD, THC, and the THC metabolites were determined after oral or inhalational administration of CBD and THC (Table 1). The [$I_{\text{int,x,ax}}$] of CBD and THC was estimated as reported previously (Ito et al., 1998) (Table 1). These concentrations were incorporated in the mechanistic model to predict the magnitude of cannabinoid-drug interactions.

Biorelevant Gastrointestinal Solubility of CBD and THC. The solubility of CBD and THC in FaSSIF buffer was $34 \pm 6.7$ and $28 \pm 5.9$ $\mu$M, respectively, and was similar to that in FeSSIF buffer ($40 \pm 2.5$ and $36 \pm 3.6$ $\mu$M, respectively). Therefore, the latter was used for all oral cannabinoid-drug interaction predictions.

Nonspecific and HLM Incubation Binding of CBD, THC, and 11-OH-THC. Nonspecific binding of CBD (0.1 and 5 $\mu$M), THC (0.5 and 5 $\mu$M), and 11-OH-THC (0.1 $\mu$M) to low-binding tubes was $69\% \pm 3\%$, $80\% \pm 9\%$, and $66\% \pm 5\%$, respectively. [$f_u,\text{inc}$] of CBD (0.1 and 5 $\mu$M), THC (0.5 and 5 $\mu$M), and 11-OH-THC (0.1 $\mu$M) was $0.12 \pm 0.04$, $0.05 \pm 0.02$, and $0.16 \pm 0.05$, respectively. These results indicated that the nonspecific and microsomal protein binding of cannabinoids was concentration-independent.

Reversible Inhibition of CYPs by CBD, THC, and THC Metabolites. CBD and THC inhibited CYP activity in a concentration-dependent manner (Figs. 2 and 3). Binding-corrected IC$_{50}$ values (IC$_{50,u}$) were determined using $f_u,\text{inc}$. Compared with CBD, THC was an approximately 7.5- and 14-times more potent inhibitor of CYP1A2 and 2C9, respectively (Table 2), but was an approximately 3.5-times less potent inhibitor of CYP3A activity (Table 2). CBD and THC showed comparable inhibitory potency toward CYP2C19 and 2D6. 11-OH-THC was a strong inhibitor of CYP2C9 and a relatively weak inhibitor of CYP2C19, 2D6, and 3A (Table 2). COOH-THC was a weak inhibitor of all CYPs tested (Table 2).

TDI of CYPs by CBD, THC, and THC Metabolites. CBD (10 $\mu$M), after preincubation for 30 minutes, showed TDI of CYP1A2, 2C19, and 3A as evidenced by a decrease in activity by $83\%$, $75\%$, and $85\%$, respectively, as compared with the vehicle-treated control group (0 minutes) (Fig. 4). THC and its metabolites did not show TDI of any of the CYPs tested (Fig. 4). Based on these data, TDI parameters for CBD toward CYP1A2, 2C19, and 3A were determined using a shorter time period to minimize CBD depletion. These parameters ($K_{\text{inax}}, K_{\text{int}},$ and $k_{\text{inax}}/K_{\text{int}}$) indicated that CBD was a time-dependent inhibitor of...
CYP1A2, 2C19, and 3A (Table 3). The efficiency (k_{inact}/K_I,u) of CBD to inactivate CYP1A2 was 5- to 6-fold greater than that for CYP2C19 or CYP3A (Fig. 5).

**Prediction of In Vivo CYP-Mediated Cannabinoid-Drug Interactions.** Based on the combined hepatic and gut AUCR values (\(\times 1.2\)) using \([I]_{\text{inlet},\text{max},u}\) for \([I]_H\) in eqs. 2 and 3 (approach 1), all tested CBD oral doses (70, 700, and 2000 mg) were predicted to precipitate pharmacokinetic interactions with theophylline, diclofenac, omeprazole, and midazolam, which are predominately metabolized by CYP1A2, 2C9, 2C19, and 3A4, respectively; the two higher doses were predicted to precipitate interactions with dextromethorphan, which is predominately metabolized by CYP2D6 (Table 4). CBD was predicted to precipitate strong interactions (AUCR > 5) with CYP2C19 and 3A substrates, even at the lowest average dose (Table 4). THC was predicted to precipitate interactions with CYP1A2, 2C9, and 3A4 substrates (AUCR > 1.2) only at high oral doses (130 and 160 mg). THC at the high average and maximum oral dose was predicted to precipitate strong interactions (AUCR > 5) with CYP2C9 substrates.

The predictions of orally administered CBD-drug interaction using \([I]_{\text{inlet},\text{max},u}\) for \([I]_H\) in inactivation term A in eq. 2 and \([I]_{\text{inlet},\text{max},u}\) for \([I]_H\) in reversible inhibition term B in eq. 3 (approach 2) yielded, as expected, lower AUCR values, but the differences were modest (except interactions between omeprazole and midazolam at 70 mg), as compared with the values predicted using approach 1 (Table 4). Inhalational THC was predicted to precipitate systemic interactions only with CYP2C9 substrates (AUCR > 1.9) (Table 4). THC

metabolites were predicted to have no interactions with any of the probe substrates (data not shown).

**Discussion**

Previous CYP inhibition studies involving CBD and THC as precipitants (Yamaori et al., 2010, 2011b; Arnold et al., 2018) did not consider the limited aqueous solubility, nonspecific binding to labware, or extensive binding to incubation protein for each cannabinoid. Therefore, the reported CYP inhibition potencies (IC<sub>50</sub> or Ki) of these cannabinoids are likely underestimated. The current work is the first to consider these properties to estimate true CYP inhibition potencies. BSA (0.2%) was added to the incubation mixtures to increase CBD or THC solubility and reduce nonspecific binding to plastic tubes and tips (Patilea-Vrana and Unadkat, 2019). Low-binding Eppendorf tubes were used to further reduce nonspecific binding. Under these optimal experimental conditions, the extent of nonspecific binding of CBD and THC in the incubation mixture (f<sub>inc</sub>) was used to determine binding-corrected inhibition potency (IC<sub>50,inc</sub> or K<sub>inc</sub>).

CBD or THC demonstrated reversible inhibition of CYP1A2, 2C9, 2C19, 2D6, and 3A activities in HLMs (Figs. 2 and 3; Table 2), consistent with previous reports (Yamaori et al., 2011a,b; Jiang et al., 2013). In the present study, the rank order of reversible inhibition (based on IC<sub>50,inc</sub> values) of the tested CYPs by CBD and THC was CYP2C9 > 2C19 ≈ 3A ≈ 1A2 > 2D6 and CYP2C9 > 1A2 > 2C19 > 2D6 ≈ 3A, respectively (Table 2). The previously reported IC<sub>50</sub> or Ki values (Yamaori et al., 2011a, 2012) are approximately 2- to 6-fold higher than those determined in the current study (Table 2), supporting low aqueous solubility and nonspecific binding of CBD and THC (Garrett and Hunt, 1974) as plausible explanations for the higher values. Another plausible explanation could reflect CYP3A5 genotype of a given lot of HLMs, as studies using recombinant enzymes suggest that CBD is a more potent inhibitor of CYP3A5 than CYP3A4 (Yamaori et al., 2011a).

The FDA recommends assessing the inhibitory effects of metabolites on CYP enzymes if the metabolite AUC exceeds parent AUC by ≥25% (https://www.fda.gov/media/134582/download). Despite the fact that the AUC of 11-OH-THC (930 µg/minute/l) and COOH-THC (14,600 µg/minute/l) is ~2.5- and ~40-fold higher, respectively, than that of THC (360 µg/minute/l) after oral administration of 10 mg THC (Nadulski et al., 2005), CYP inhibition potency of these metabolites has not been determined. The present study is the first to determine the IC<sub>50,inc</sub> of 11-OH THC and COOH-THC against CYP enzymes. 11-OH THC was a reversible inhibitor of CYP2C9, 2C19, 2D6, and CYP3A, but the IC<sub>50,inc</sub> values were much greater than those for THC, whereas COOH-THC did not inhibit any of the CYPs by an appreciable extent.

The efficiency of CBD to inactivate multiple CYPs in HLMs was determined for the first time. CBD was a time-dependent inhibitor of three CYPs, showing the strongest inhibition against CYP1A2, followed by 2C19 and 3A (Fig. 5). Previously, only the efficiency of TDI (k<sub>max</sub>/K<sub>i</sub>) of CYP1A2 by CBD had been reported (0.19 minutes<sup>-1</sup>/μM<sup>-1</sup>) (Yamaori et al., 2010), which was ~3.5-times lower than that

Fig. 4. TDI of CYPs by CBD, THC, 11-OH-THC, and COOH-THC. When the cannabinoids were preincubated with HLMs only, CBD showed TDI of CYP1A2, 2C19, and 3A. Pooled HLMs (0.5 mg/ml protein) were preincubated with NADPH regenerating system, cannabinoid (THC, CBD, 11-OH-THC or COOH-THC; 10 µM), or vehicle (0.2% v/v DMSO) at 37°C for 0, 10, 20, or 30 minutes. Then, an aliquot (10 µl) of this mixture was incubated with NADPH regenerating system and a CYP substrate cocktail consisting of phenacetin (CYP1A2; 50 µM), diclofenac (CYP2C9; 5 µM), omeprazole (CYP2C19; 20 µM), dextromethorphan (CYP2D6; 5 µM), and testosterone (CYP3A; 20 µM) for 15 minutes. Data represent percent of activity in the vehicle-treated control group (0 minutes) that was not subjected to preincubation and are shown as means ± S.D for three independent experiments. *P < 0.05, significantly different from the vehicle-treated control group (two-way analysis of variance test).
Because this metric cannot be measured directly, study were comparable to that of furafylline (represent percent of activity in the vehicle-treated control group (0 minutes) that was not subjected to preincubation and are shown as means ± S.D. for four independent experiments. (B) Nonlinear regression model fits of the experiments. (B) Nonlinear regression model fits of the

![Fig. 5. TDI of CYP1A2, 2C19, and 3A by various concentrations of CBD. The order of CBD inactivation potency was CYP1A2 > 2C19 ≈ CYP3A (Table 3).](image)

(A) Pooled HLMs (0.5 mg/ml protein) were preincubated with NADPH regenerating system, CBD (0.5, 1, 2.5, 5, 10, 20, 40, or 60 μM), or vehicle (0.2% v/v DMSO) at 37°C for 0, 4, 8, 12, or 16 minutes. Then, an aliquot (10 μl) of this mixture was incubated with NADPH regenerating system and a CYP substrate cocktail consisting of phenacetin (CYP1A2; 50 μM), diclofenac (CYP2C9; 5 μM), omeprazole (CYP2C19; 20 μM), dextromethorphan (CYP2D6; 5 μM), and testosterone (CYP3A; 20 μM) for 15 minutes. I. However, we were unable to find these values for furafylline and ritonavir in the literature. Unlike CBD, THC, 11-OH-THC, and COOH-THC showed no difference likely attributed to CBD nonspecific binding and poor aqueous solubility. Comparatively, $k_{\text{inact}}/K_i$ for CBD (0.074 minutes⁻¹/μM⁻¹) and $k_{\text{inact}}/K_{\text{u}}$ for CBD (0.11 minutes⁻¹/μM⁻¹) in the present study were comparable to that of furafylline ($k_{\text{inact}}/K_i$ = 0.12 minutes⁻¹/μM⁻¹) (Obach et al., 2007) and ticlopidine ($k_{\text{inact}}/K_{\text{u}}$ = 0.17 minutes⁻¹/μM⁻¹) (Nishiya et al., 2009), the prototypic time-dependent inhibitors of CYP1A2 and 2C19, respectively. In contrast, CBD ($k_{\text{inact}}$ was approximately 90-times less efficient than raronavir ($k_{\text{inact}}/K_i = 1.55$ minutes⁻¹/μM⁻¹) as a time-dependent inhibitor of CYP3A (Obach et al., 2007). These comparisons should ideally be made using the unbound $K_i$. However, we were unable to find these values for furafylline and ritonavir in the literature.

Unlike CBD, THC, 11-OH-THC, and COOH-THC showed no modulation of any of the CYPs tested, suggesting a role for the hydroxy group of the resorcinol moiety in CBD [absent in THC, 11-OH-THC, or COOH-THC (Fig. 1)] in the TDI of CYP1A2, 2C19, and 3A. The mechanism(s) of CYP TDI by CBD is not known but could involve the formation of CBD-hydroxyquinone as reported for TDI of murine CYP3a11 (Bornheim and Grillo, 1998).

Knowledge of the unbound concentration of an inhibitor/inactivator $[I]$ at the target enzyme is needed to predict a drug interaction accurately. Because this metric cannot be measured directly, $[I]_{\text{max},u}$ or $[I]_{\text{inlet},u}$ was used as a surrogate of $[I]$ in the liver. The drug interaction potential of each cannabinoid after oral administration was predicted using $[I]_{\text{inlet},u}$ (for both reversible and time-dependent inhibition) and using both $[I]_{\text{inlet},u}$ and $[I]_{\text{max},u}$ (for both reversible as well as time-dependent inhibition, respectively). The latter approach has been shown to better predict the magnitude of drug interactions for inhibitors that are reversible and time-dependent inhibitors of CYPs (Ito et al., 2004; Obach et al., 2006, 2007). After THC inhalation, AUCR predictions were made using $[I]_{\text{max},u}$ (Table 4). To predict the magnitude of cannabinoid-drug interactions in the intestine, the maximum intestinal fluid solubility ([I]c), determined using FeSSIF buffer, was used as a surrogate for the concentration available in the intestine to inhibit CYP2C9 and 3A.

CBD was predicted to precipitate strong drug interactions (AUCR ≥ 5) mediated by CYP2C9, 2C19, and 3A and moderate drug interactions (1.2 ≤ AUCR < 5) mediated by CYP1A2 and 2D6 based on the AUC cutoffs recommended by the FDA (https://www.fda.gov/media/134582/download). These predictions are largely consistent with clinical CBD- or THC-drug interactions reported in the literature. For example, oral administration of CBD (5–25 mg/kg per day) with the anticonvulsant zolpidem led to a marked increase (about fivefold) in plasma concentrations of the metabolite N-desmethyloclobazam, which is metabolized predominantly by CYP2C19 (Geoffrey et al., 2015; Gaston and Szaflarski, 2018). Oral administration of CBD (750 mg twice daily) with clobazam and stiripentol (a CYP2C19 substrate) led to a 3.4- and 1.6-fold increase in N-desmethyloclobazam and stiripentol AUC, respectively (Morrison et al., 2019). Likewise, oral CBD (600 mg/day for 5–12 days) increased the AUC (by 51%) of oral hexobarbital, which is partially cleared by CYP2C9 (Benowitz et al., 1980). In addition, one case report described an increased international normalized ratio when CBD was coadministered with warfarin (Grayson et al., 2017), which is cleared largely by CYP2C9. In contrast, although a strong interaction between CBD and oral midazolam was predicted, there was minimal change in the AUC of midazolam after chronic administration of CBD (250 mg/day on days 1–11, 750 mg twice/day on days 12–25) (https://www.accessdata.fda.gov/drugsatfda_docs/nda/2018/210365Orig1s000ClinPharmR.pdf). Possible induction of
CYP3A4 (mRNA) by CBD in human hepatocytes (https://www.accessdata.fda.gov/drugsatfda_docs/nda/2018/210365Orig1s000ClinPharmR.pdf) may explain this discrepancy.

After oral administration, THC was predicted to produce strong CYP2C9-mediated (AUCR $> 5$) but weak CYP1A2- and 3A-mediated (AUCR $< 2$) drug interactions. After inhalation, THC was predicted to produce drug interactions only with drugs extensively metabolized by CYP2C9. A case report involving THC and warfarin supports this prediction (Yamreudeewong et al., 2009), in which the patient’s international normalized ratio increased to 11.55 because of frequent cannabis smoking. In contrast, regardless of the inhaled THC dose, neither 11-OH-THC nor COOH-THC was predicted to precipitate interaction with CYP2C9, 2C19, 2D6, or 3A substrates (Table 4).

There are several limitations to the current work. First, the depletion of CBD or THC during the incubations was not considered when estimating IC$_{50}$ or $K_I$ values. Thus, these observed values may be higher than the true IC$_{50}$ or $K_I$ values. Second, when determining the IC$_{50}$ for CBD, the possibility of simultaneous TDI of CYP1A2, 2C19, or 3A during the incubation period cannot be discounted. This scenario could result in estimation of lower IC$_{50}$ values than the true values. Third, our drug interaction predictions are based on maximum cannabinoid plasma concentrations, which remain static. In humans, plasma concentrations of CBD and THC decrease rapidly after inhalation, whereas after oral administration, the decrease is more gradual (Ohlsson et al., 1986; Huestis, 2007). As such, PBPK modeling and simulation of cannabinoid-drug interactions is underway to capture these dynamic changes. These PBPK models should lead to improved predictions of interactions mediated by the formation of 11-OH-THC and COOH-THC during first pass. Although the majority of marijuana products on the market are either CBD rich or THC rich, there are some
products that contain both CBD and THC. Based on the data presented here, drug interaction when both are simultaneously present can be predicted using PBPK modeling and simulation. Previously, CBD was reported to inhibit CYP2B6, 2C8 (https://www.accessdata.fda.gov/drugsatfda_docs/nda/2018/210365Orig1s000ClinPharmR.pdf); Yamaori et al., 2011), and non-CYP enzymes such as UGT1A9 and 2B7 (https://www.accessdata.fda.gov/drugsatfda_docs/nda/2018/210365Orig1s000ClinPharmR.pdf). Potential interactions between CBD and drugs metabolized by these enzymes as well as drug transporters such as P-glycoprotein and breast cancer–resistance protein should also be evaluated (Alsherbiny and Li, 2018).

In conclusion, a combined mechanistic state model predicted a moderate to strong pharmacokinetic interaction risk between orally administered CBD and drugs extensively metabolized by CYP1A2, 2C9, 2C19, 2D6, or 3A and between orally administered THC and drugs extensively metabolized by CYP1A2, 2C9, or 3A. With respect to inhalational administration, THC was predicted to produce interactions only with drugs extensively metabolized by CYP2C9. These predictions need to be verified by a well designed clinical drug interaction study using prototypic CYP substrates.
