Abbreviations: AUC, area under the plasma concentration-time curve; B/P, blood-to-plasma; Cl, clearance; Clₘ, metabolic clearance; Clᵣ, renal clearance; DIDS, 4,4′-diisothiocyanostilbene-2,2′-disulfonate; GHB, γ-hydroxybutyrate; MCT, monocarboxylate transporter; pCMBS, p-chloromercuribenzenesulfonate; RBC, red blood cell; SMCT, sodium-coupled monocarboxylate transporter
Abstract

The drug of abuse γ-hydroxybutyrate (GHB) displays nonlinear renal clearance which has been attributed to saturable renal reabsorption by monocarboxylate transporters (MCTs) present in the kidney. MCT1 is also present on red blood cells (RBCs); however the significance of this transporter on the blood/plasma partitioning of GHB is unknown. The purpose of this research was to characterize the transport of GHB across the RBC membrane and assess GHB blood/plasma partitioning in vivo in the presence and absence of a competitive MCT inhibitor, L-lactate. In vitro experiments were performed using freshly isolated rat erythrocytes at pH values of 6.5 and 7.4. Inhibition with pCMBS and DIDS were used to determine the contribution of MCT1 and band 3, respectively, on GHB uptake. For in vivo experiments, rats were administered GHB (400-1500 mg/kg) with and without L-lactate. In vitro experiments demonstrated that GHB is transported across the RBC membrane primarily by MCT1 at relevant in vivo concentrations. The $K_m$ for MCT1 was lower at pH 6.5 than that at pH 7.4, 2.2 vs. 17.0 mM, respectively. The in vivo blood/plasma partitioning of GHB displayed linearity across all concentrations. L-lactate co-administration increased GHB renal clearance but had no effect on the blood/plasma ratio. Unlike its MCT-mediated transport in the intestine and kidneys, GHB blood/plasma partitioning appears to be linear and is unaffected by L-lactate. These findings can be attributed at least in part to differences in physiologic pH at different sites of MCT-mediated transport.
Introduction

Endogenously produced via γ-aminobutyric acid metabolism, γ-hydroxybutyrate (GHB) is a short-chain fatty acid naturally present in several mammalian tissues, including the brain (Maitre, 1997). GHB is used therapeutically in the U.S. for the treatment of narcolepsy with cataplexy as sodium oxybate (Xyrem®) and for the treatment of alcohol withdrawal in Europe (Gallimberti et al., 2000). GHB has also recently been recognized as a common drug of abuse. Overdose cases involving GHB and its precursors, 1,4-butanediol and γ-butyrolactone, have been reported in the U.S. and other western countries resulting in GHB-induced coma, respiratory depression, and fatality (Caldicott et al., 2004; Zvosec et al., 2010).

Even at low, therapeutic doses GHB displays nonlinear pharmacokinetics in humans (Palatini et al., 1993). In rats, this dose-dependence has been demonstrated to be due to saturable metabolism, saturable oral absorption, and saturable renal reabsorption (Lettieri and Fung, 1979; Arena and Fung, 1980; Morris et al., 2005). Saturable oral absorption and renal reabsorption have been explained by the concentration-dependent transport of GHB by monocarboxylate transporters (MCTs) (Morris et al., 2005; Wang et al., 2006; Lam et al., 2010). MCTs are proton-coupled transporters with ubiquitous expression, including expression at the intestine, kidney, brain, and at the red blood cell (RBC) membrane. Human and rodent RBCs primarily express MCT1 and have been used extensively for the characterization of this transporter (Poole and Halestrap, 1993; Garcia et al., 1995; Merezhinskaya and Fishbein, 2009). Although MCT-mediated transport has been demonstrated to govern several of the pharmacokinetic processes of GHB, the significance of transport by MCT1 at the RBC membrane is unknown. The blood/plasma partitioning of GHB, including the linearity of this partitioning over relevant therapeutic and overdose concentrations, has not been evaluated.
Transport of other monocarboxylates, most notably lactate, across the RBC membrane has been well-characterized. Lactate RBC transport has been demonstrated to be due to three distinct mechanisms: transport by MCT1, transport by the anion exchanger, AE1 or band 3, and passive diffusion, which is demonstrated to be minimal (Deuticke et al., 1982). At physiologic lactate concentrations, MCT-mediated transport has been identified as the primary mode of lactate transport across human and rat RBC membranes with band 3 transport being prominent at very high (>300 mM) lactate concentrations (Deuticke et al., 1978; Deuticke et al., 1982; Poole and Halestrap, 1993).

GHB is a known MCT substrate; however, transport by band 3 has not been previously evaluated, and the relative contribution of these transporters to GHB transport across the RBC membrane is not known.

Increasing incidence of GHB abuse has been reported in the U.S. with no pharmacological treatment currently identified to treat GHB overdose. Due to MCT-mediated renal reabsorption of GHB, increasing renal clearance via MCT inhibition represents a potential treatment strategy in GHB overdose cases. The co-administration of GHB with L-lactate and other MCT inhibitors has been demonstrated to be effective in our laboratory for increasing renal and total clearances of GHB in rats (Morris et al., 2005; Wang et al., 2008a; Wang et al., 2008b). Due to ubiquitous MCT expression which governs GHB pharmacokinetics, in vivo administration of MCT inhibitors has the potential to affect other pharmacokinetic parameters of GHB along with that of renal clearance. There exists a lack of information regarding the in vivo blood/plasma partitioning of GHB, and as such the effect of MCT inhibitors on this partitioning is also unidentified. The purpose of this research was to characterize the transport of GHB at the RBC membrane and to determine GHB blood/plasma partitioning in vivo in the presence and absence of the competitive MCT inhibitor L-lactate.
Methods

Chemicals and Reagents. Sodium GHB used in these studies was provided by the National Institute on Drug Abuse (NIDA). $^3$H-GHB was purchased from American Radiolabeled Chemicals, Inc. (St. Louis, MO). Deuterated GHB (GHB-d6) was obtained from Cerilliant (Round Rock, TX). Sodium L-lactate, silicone oil, and 4,4'-diisothiocyanostilbene-2,2'-disulfonate (DIDS) were purchased from Sigma-Aldrich (St. Louis, MO). p-chloromercuribenzenesulfonate (pCMBS) was purchased from Toronto Research Chemicals, Inc. (North York, ON). All other chemicals were of analytical grade.

Animals and Animal Surgery. Male Sprague-Dawley rats (Harlan Laboratories, Indianapolis, IN) weighing 270-330 g were used for in vivo experiments. Animals were housed under controlled temperature and humidity with an artificial 12 hour light/dark cycle and food was available ad libitum. All animal protocols were approved by the Institutional Animal Care and Use Committee at the University at Buffalo. Animals were allowed to acclimate to their environment for one week prior to any surgical procedure. All surgery was performed under anesthesia with ketamine/xylazine. Animals administered GHB alone underwent implantation of a jugular vein cannula, and those administered GHB and L-lactate underwent implantation of jugular and femoral vein cannulae. Cannulae were flushed daily with 40 IU/mL heparinized saline to maintain patency. All animals were allowed a minimum of 72 hours for recovery from surgery before drug administration.

In vivo Experimental Protocol. To assess the in vivo blood/plasma (B/P) partitioning of GHB and the effect of L-lactate on the GHB B/P ratio, serial as well as sacrificial sampling studies were performed. In the first study, animals were sacrificed and blood and plasma collected at 10, 30, 60, 120, 150, 180, 210, 240, and 300 minutes after intravenous GHB administration at doses of 400, 600, and 800 mg/kg (n=3 for each dose at each time point). Another set of animals was administered GHB 600 mg/kg
intravenously and L-lactate as a 330 mg/kg bolus followed by a 121 mg/kg/hr infusion and sacrificed at the same time points. In the second study, to assess individual blood/plasma ratios across a wide concentration range, along with individual GHB renal clearances, animals were administered GHB 1500 mg/kg intravenously and blood and plasma serially collected at 3, 10, 20, 30, 60, 120, 150, 180, 210, 240, 270, 300, 330, and 360 minutes. Urine samples were also collected at determined intervals up to 480 minutes. Another set of animals was administered GHB 1500 mg/kg intravenously and L-lactate as a 66 mg/kg bolus followed by a 302.5 mg/kg/hr infusion and samples were serially collected as for GHB alone. For serial sampling, n=4-5 animals per group. In each study, L-lactate was administered 5 minutes after GHB administration. GHB was administered via the jugular vein cannula as a 200 or 300 mg/ml solution in water. L-lactate infusions were administered using a PicoPlus syringe pump (Harvard Apparatus, Holliston, MA) as a 20 or 40 mg/mL solution in water via the femoral vein cannula.

**Sample Analysis by LC/MS/MS.** Sample Preparation. GHB blood, plasma, and urine concentrations were determined using a previously validated LC/MS/MS assay (Felmlee et al., 2010a; Felmlee et al., 2010b) with slight modification for blood sample analysis. For preparation of blood and plasma standards, 50 μL of blank blood or plasma was added to 5 μL GHB standard solution and 5 μL GHB-d6. For samples, 50 μL of sample was added to 5 μL double-distilled water and 5 μL GHB-d6. Protein precipitation was then performed by the addition of 400 μL acetonitrile and samples were centrifuged at 10,000 rpm for 20 minutes. For blood samples, red blood cell lysis was first performed with the addition of 100 μL double-distilled water followed by protein precipitation with 300 μL acetonitrile and centrifugation. An aliquot of the resulting supernatant (200 μL) was removed and diluted with 800 μL double-distilled water, and the diluted samples extracted using an anion solid phase extraction procedure previously described (Raybon and Boje, 2007) using Bond Elut SAX cartridges (100 mg resin, 1 mL volume, Agilent
Technologies, Palo Alto, CA). The samples were then dried under nitrogen gas and reconstituted with aqueous mobile phase. For urine samples, 50 μL of blank urine or urine sample was added to 10 μL GHB-d6 and 10 μL standard solution or double-distilled water. Protein precipitation was then performed by the addition of 930 μL double-distilled water followed by 1 mL acetonitrile and centrifugation at 10,000 rpm for 20 minutes. An aliquot of the resulting supernatant (1.25 mL) was used for analysis by LC/MS/MS.

**Sample Analysis.** The same LC/MS/MS method was used for GHB blood, plasma, and urine analyses. LC/MS/MS equipment consisted of an Agilent 1100 series HPLC including an online degasser, binary pump and autosampler (Agilent Technologies, Palo Alto, CA) which was connected to a PE Sciex API 3000 triple-quadrupole tandem mass spectrometer with a turbo ion spray (Applied Biosystems, Foster City, CA). Seven microliters of sample was injected onto an Xterra MS C18 column (250x2.1 mm id, 5 um particle size, Water Co., Milford, MA). GHB was eluted with a flow rate of 0.2 mL/min, 100 to 90% A over 5 min, 90 to 10% A from 5-7.5 min, and 10 to 100% A from 7.5-12 min. Mobile phase A was made up of 0.1% formic acid in 95/5 water/acetonitrile. Mobile phase B was made up of 0.1% formic acid in 5/95 water/acetonitrile. The limit of quantification for blood and plasma was 1 μg/mL and 4 μg/mL for urine. Mass spectrometer conditions and calibration ranges have been described previously (Felmlee et al., 2010a). L-lactate plasma concentrations were determined by a YSI 1500 Sport Lactate Analyzer (Yellow Springs Instruments, Inc., Yellow Springs, OH).

**In Vitro Uptake.** Freshly isolated erythrocytes from male Sprague-Dawley rats (Harlan Laboratories, Indianapolis, IN) were used for in vitro experiments. Blood was withdrawn from animals sacrificed under isofluorane anesthesia. After removal of the plasma and buffycoat, erythrocytes were washed 3 times in uptake buffer for removal of extracellular lactate. Uptake buffer consisted of 137 mM NaCl, 5.4 mM KCl, 2.8 mM CaCl₂, 1.2 mM
MgCl₂, and 10 mM HEPES at the specified pH values. Red blood cells were then made into a 40% suspension in uptake buffer. For uptake, an oil-stop technique was used similar to those previously described (Jarvis and Young, 1980; Endres et al., 2009). To initiate transport, 50 μL of the red blood cell suspension was spiked into 200 μL uptake buffer containing various concentrations of ³H-GHB. Transport was stopped by transferring 150 μL of this resulting suspension to centrifuge tubes containing 350 μL ice-cold stop buffer (137 mM NaCl, 5.4 mM KCl, 2.8 mM CaCl₂, 1.2 mM MgCl₂, 10 mM HEPES at pH 7.4) over 200 μL silicone oil (s.g 1.05). Tubes were then centrifuged and the oil and buffer were aspirated off. Red blood cells were washed 3 times with ice-cold uptake buffer for removal of extracellularly bound ³H-GHB. Cells were then lysed with 1 mL double-distilled water and 500 μL of the lysate transferred to vials with 3 mL scintillation fluid for measurement of radioactivity. Radioactivity was measured using a 1900CA Tri-Carb liquid scintillation analyzer (Packard Instrument Co., Meriden, CT). Total protein content of the RBC lysate was determined by spectrophotometry. Initial time-dependent uptake was used to determine the linear range of GHB uptake at each pH value. For determination of the transporters involved in GHB transport, specific inhibitors were used. To inhibit MCT1, the red blood cell suspension was incubated in 1 mM pCMBS for 1 hour prior to addition of ³H-GHB. For band 3 inhibition, at pH 7.4 the red blood cell suspension was incubated in 10 μM DIDS for 5 minutes prior to addition of ³H-GHB. Although DIDS is also capable of inhibiting MCTs, this concentration has been demonstrated to completely inhibit anion transport by band 3 (Halestrap, 1976), while still much lower than the IC₅₀ value for rMCT1 (Poole and Halestrap, 1991). To determine an inhibition constant for L-lactate, uptake of 10 mM GHB was assessed in the presence of various L-lactate concentrations at pH 7.4. Unless otherwise specified, in vitro experiments were performed at room temperature in triplicate and repeated 3 times.
Data and Statistical Analysis. In vivo blood and plasma GHB concentrations were plotted against one another and the blood/plasma ratios determined by linear regression. Total clearance (Cl) was calculated as Dose/AUC where AUC represents the plasma AUC$_{0-\infty}$, determined by noncompartmental analysis using WinNonlin 5.2 (Pharsight Corporation, Palo Alto, CA). Renal clearance (Cl$_R$) was determined as Ae/AUC, where Ae represents the total amount excreted in the urine. Metabolic clearance (Cl$_m$) was calculated as Cl-Cl$_R$. The blood/plasma ratios and clearance values for animals administered 1500 mg/kg GHB with and without L-lactate were compared to determine any statistically significant effect of L-lactate administration on these GHB pharmacokinetic parameters. Statistical comparisons were made using student’s t-tests or Mann-Whitney rank sum tests using SigmaPlot 10.0 (Systat Software, Inc., San Jose, CA). Using WinNonlin, in vitro GHB concentration-dependent uptake was fitted with equation (1) and inhibition by L-lactate with equation (2):

\[
Uptake = \frac{V_{max} \cdot C}{K_n + C} + P \cdot C
\]

(1)

\[
Uptake = Control \cdot \left(1 - \frac{I_{max} \cdot C^\gamma}{IC_{50}^\gamma + C^\gamma}\right)
\]

(2)
Results

*In vivo GHB blood/plasma partitioning.* The in vivo blood/plasma partitioning is shown in Figure 1 and resulting B/P ratios in Table 1. This partitioning appears linear over the entire in vivo range of concentrations. Concomitant L-lactate administration resulted in a similar B/P ratio as that for GHB alone. Comparing animals in which individual B/P ratios could be obtained due to serial sampling, the mean blood/plasma ratios were similar to that using pooled data from both sampling strategies, indicating that these ratios were representative of the entire dataset. From this set of experiments, the mean B/P ratio in animals administered GHB with L-lactate was not significantly different from that of animals administered GHB alone. However, in the same animals, this dose of L-lactate significantly increased renal and total clearances of GHB compared to that of GHB alone (Figure 2). Lactate concentrations achieved with both L-lactate regimens are shown in Figure 3.

*In vitro GHB uptake.* Based upon time-dependent experiments, 5 and 15 seconds were used for concentration-dependent experiments at pH values of 6.5 and 7.4, respectively. Concentration-dependent uptake at each pH is shown in Figure 4. At both pH values, incubation of the cell suspension with pCMBS resulted in complete inhibition of the saturable transport component, indicating that all saturable transport within this range of GHB concentrations is due to MCT-mediated transport. Inhibition of band 3 with DIDS at pH 7.4 resulted in inhibition of the linear transport component, indicating that this component is due to band 3-mediated transport. The resulting transport with DIDS inhibition was similar to that simulated with the Vₘₐₓ and Kₘ for MCT-mediated transport, suggesting that total transport can be accounted for by these two transporters. The contribution of MCT-mediated transport, determined by transport inhibited by pCMBS at pH 7.4, is given in Table 2. At the lower GHB concentrations, relevant to in vivo GHB concentrations, incubation with pCMBS resulted in inhibition of ~75% of total transport,
indicating that MCT-mediated transport is the primary mechanism responsible for RBC membrane transport of GHB in vivo. Total transport and transport in the presence of pCMBS at pH 7.4 were simultaneously fitted with nonlinear regression resulting in values of 17.0 mM, 20.9 nmol/mg/min and 0.24 μL/mg/min for $K_m$, $V_{max}$, and $P$ at pH 7.4. Fitting the total and pCMBS-inhibited transport at pH 6.5 resulted in a much lower $K_m$ value of 2.2 mM, with $V_{max}$ and $P$ values of 5.3 nmol/mg/min and 0.11 μL/mg/min, respectively. Fitting GHB transport in the presence of L-lactate resulted in an IC50 value for L-lactate of 19.1 mM (Figure 5). No significant inhibition was observed at L-lactate concentrations at or below 5 mM.
Discussion

Although saturable, carrier-mediated oral absorption and renal reabsorption of GHB have been demonstrated and attributed to MCT-mediated transport, the linearity and effect of MCTs on the distribution of GHB have not been fully investigated. In situ experiments indicate a role of MCT1 in the distribution of GHB into the brain (Bhattacharya and Boje, 2004); however, the significance of this transport in vivo has not been determined. The intracellular RBC space can contribute considerably to drug distribution. Here, we demonstrate the significance of MCT-mediated transport of GHB into RBCs in vitro and have assessed the distributive effects of this transport in vivo. Our in vivo experiments demonstrate linearity in GHB blood/plasma partitioning along with a lack of effect of L-lactate administration on this parameter. These results are surprising considering the nonlinearity of MCT-mediated renal clearance at these GHB doses and ability of L-lactate to increase this clearance, demonstrated in this and other studies (Morris et al., 2005; Wang et al., 2008a). To further investigate these findings, we performed in vitro experiments to determine the contribution of MCT-mediated transport in RBCs at relevant in vivo GHB concentrations and the effect of changes in pH at the transport site. Results of these in vitro experiments demonstrate that at relevant in vivo concentrations (<40 mM), the majority of GHB transport across the RBC membrane is MCT-mediated. These in vitro experiments also demonstrate a decrease in the affinity of GHB for MCT1 as pH increases, indicated by a much lower $K_m$ value at pH 6.5 compared to that at pH 7.4. A similar trend for L-lactate transport has been noted previously (Deuticke, 1982), and our experiments confirm this effect of pH on MCT-mediated transport of GHB. Likewise, although inhibition of GHB transport by 2 mM L-lactate in rat kidney membrane vesicles expressing rMCT1 has been demonstrated at pH 5.5 (Wang et al., 2006), our current experiments at pH 7.4 demonstrate no inhibition of GHB transport at this and other relevant in vivo L-lactate concentrations. These in
vitro findings can explain our results observed in vivo. Considering a decrease in GHB and L-lactate affinity for MCT1 at physiologic blood pH compared to that of the lower pH in the renal tubule, nonlinearity and inhibition could be expected to occur in the kidney at doses in which these effects are not observed at the RBC membrane.

The resulting $K_m$ for GHB of 17.0 mM determined at pH 7.4 is considerably higher than that previously determined for rMCT1 in our laboratory of 4.6 mM (Wang et al., 2006). This reported $K_m$ value of 4.6 mM was determined at pH 6.0 and, as the current study demonstrates, this value would be expected to be lower than that at pH 7.4. The reported value is similar to our currently reported value of 2.2 mM at pH 6.5 and is more relevant to MCT-mediated transport at the kidney rather than that in the blood. A $K_i$ value for L-lactate has also been previously determined, for inhibition of its own transport in rat RBCs at pH 7.4, to be 2.2 mM (Poole et al., 1990), a value much lower than our currently reported value of 19.1 mM. Although the reported $K_i$ value was assessed as physiologic blood pH, this value was determined at a very low temperature (6°C) due to rapid lactate transport kinetics. The values of $K_i$ and $K_m$ for MCT substrates have been observed to increase with temperature; several-fold differences have been reported as temperature is increased from 5 to 20°C (Deuticke, 1982; Poole and Halestrap, 1993). The $IC_{50}$ value determined at a higher temperature in our studies is expected to be much greater than the previously reported $K_i$ value. Our in vitro results, at a more relevant temperature, demonstrate no inhibition of GHB transport at the L-lactate concentrations reached in vivo, consistent with a lack of inhibition at the RBC in our in vivo studies.

Along with the effect of pH, other factors may contribute to the observed in vivo results, including the presence of sodium-coupled monocarboxylate transporters (SMCTs, SLC5A8 and SLC5A12) in the kidney, which transport both GHB and L-lactate (Ganapathy et al., 2008). Previous experiments in this laboratory demonstrated that the $K_m$ and $IC_{50}$ values of GHB and L-lactate for SMCT1 are lower than that for MCT1 (Cui
and Morris, 2009); therefore, transport by SMCTs in the kidney likely plays a role in the nonlinearity of GHB renal clearance and inhibition by L-lactate. Expression of SMCTs on RBCs has not been demonstrated, and this may also contribute to the observed differences in transport at the RBC and in the kidney. While blood/plasma partitioning displayed linearity, GHB plasma concentrations reached in our in vivo experiments were greater than our reported $K_m$ value of 17.0 mM at pH 7.4; therefore, it is assumed that there are additional effects at the RBC membrane preventing saturation of GHB transport at this site. Bidirectional MCT-mediated transport and trans-stimulation may contribute to the observed linearity at this membrane, as this phenomenon has been demonstrated to occur with monocarboxylates in RBCs (Halestrap, 1976). Trans-stimulation may prevent saturation at steady-state in vivo, while this effect would not be observed in our unidirectional uptake experiments. Indeed, the $K_m$ and $V_{max}$ of L-lactate measured under equilibrium exchange have been shown to be much higher than that determined by unidirectional uptake or efflux (Deuticke, 1982); therefore this is likely also true for GHB. Additionally, due to rapid transport kinetics, in vitro experiments were performed at a temperature lower than the physiologic temperature of 37°C. Considering the discussed effects of temperature on MCT-mediated transport, the actual in vivo $K_m$ for GHB uptake may in fact be higher than our determined value at pH 7.4. Along with MCT-mediated transport, in vitro experiments also indicate that band 3 plays a role in GHB RBC transport. Although this transport contributes at high GHB concentrations, it is unlikely that this transport alone would explain the lack of saturation at the RBC membrane in vivo, as this effect would also be expected to occur in vitro, and was not observed in our studies.

In conclusion, the contribution of MCT-mediated transport of GHB at the red blood cell has been demonstrated to be significant at relevant in vivo concentrations, although this transport does not appear to be saturable with in vivo GHB administration.
Similarly, while intravenous L-lactate administration inhibits GHB transport in the kidney, this MCT inhibitor appears to have no effect on GHB distribution into RBCs at relevant plasma concentrations. The difference in pH at these transport sites likely contributes to these observations, although other effects may be involved. This work emphasizes the need to consider physiologic conditions, particularly pH, when translating in vitro MCT transport kinetics to in vivo effects on drug pharmacokinetics.

Figure 1. In vivo blood/plasma partitioning of GHB in the presence and absence of L-lactate. Data include those of both serial and sacrificial sampling in rats following intravenous GHB administration in doses of 400-1500 mg/kg with and without one of two L-lactate doses, 330 mg/kg followed by 121 mg/kg/hr or 66 mg/kg followed by 302.5 mg/kg/hr (n=74 total).

Figure 2. Clearance of GHB in rats administered GHB with and without L-lactate. GHB was administered intravenously at 1500 mg/kg followed by L-lactate as a 66 mg/kg bolus and 302.5 mg/kg/hr infusion. Cl=clearance, Clm=metabolic clearance, ClR=renal clearance. Data are presented as mean +/- SD (n=4-5/group). Clearances between groups administered GHB alone and with L-lactate were compared using student’s t-tests or Mann-Whitney rank sum tests. * indicates a statistically significant difference (p-value<0.05).

Figure 3. Plasma L-lactate concentrations following concomitant L-lactate and GHB administration. L-lactate was administered 5 minutes after GHB administration, time 0. Closed symbols represent data from serially sampling for up to 360 minutes in rats administered intravenous GHB 1500 mg/kg + L-lactate 66 mg/kg followed by 302.5 mg/kg/hr (n=4 total). Open symbols represent data from rats sacrificed at up to 210 minutes after intravenous administration of 600 mg/kg GHB + L-lactate 330 mg/kg followed by 121 mg/kg/hr (n=3 at each time point). Data are presented as mean +/- SD.

Figure 4. Concentration-dependent uptake of GHB in rat RBCs. A, uptake at pH 7.4; B, uptake at pH 6.5. Closed circles=total transport, open circles=transport in the presence of 1 mM pCMBS, closed triangles=transport in the presence of 10 uM DIDS.
Data are presented as mean +/- SEM. Total transport and transport in the presence of pCMBS were simultaneously fitted by nonlinear regression represented by the solid (total transport) and dashed (pCMBS) lines. Dotted line=simulated MCT-mediated transport using fitted $K_m$ and $V_{max}$ values.

**Figure 5. Concentration-dependent inhibition of GHB red blood cell uptake by L-lactate.** Closed circles represent uptake of 10 mM GHB at pH 7.4 at the respective L-lactate concentration. Solid line represents fitting with equation (2). Results are from two experiments performed in triplicate. Data presented as mean +/- SEM. Inset displays effect of measured in vivo L-lactate concentrations ($\leq$ 5mM) on GHB transport compared to control (0 mM).

Using a student’s t-test, no significant difference was determined between animals administered GHB 1500 mg/kg compared to those administered GHB 1500 mg/kg + L-lactate (p-value>0.05).

† Ratio determined using data from all animals, including serial and sacrificial sampling studies (n=74 rats total) and both L-lactate doses (330 mg/kg +121 mg/kg/hr and 66 mg/kg + 302.5 mg/kg/hr). No SD was determined since sacrificial sampling did not allow determination of individual B/P ratios across a concentration range.

†† Mean of individual B/P ratios determined from serial sampling study only (n=4-5 in each group). These values were used for statistical comparison.

![Graph showing the relationship between blood and plasma concentrations of GHB and GHB + L-lactate.](image-url)
Fig. 2

![Bar graph showing Cl (mL/kg/min) for GHB and GHB+Lactate conditions with Clm, CIR, and total Cl](image)

- GHB:
  - Clm
  - CIR
  - Total Cl

- GHB+Lactate:
  - Clm
  - CIR
  - Total Cl

*Significant difference compared to GHB condition.
Fig. 3

L-lactate 66 mg/kg + 302.5 mg/kg/hr
L-lactate 330 mg/kg + 121 mg/kg/hr

Mean plasma [lactate] (mM) vs. Time (min)
Fig. 5

Uptake (nmol/mg/min) vs. [L-lactate] (mM)

- The graph shows the uptake of L-lactate at various concentrations, with error bars indicating variability.
- The data points are connected by a smooth curve, suggesting a decay-like relationship.
- The inset graph provides a closer view of the relationship at lower concentrations.
