In Vitro Metabolism of the Glucagon-Like Peptide-1 (GLP-1)-Derived Metabolites GLP-
1(9-36)amide and GLP-1(28-36)amide in Mouse and Human Hepatocytes

Abbreviations used are: GLP-1, glucagon-like peptide-1; $t_{1/2}$, half-life; DPP-IV, dipeptidyl-peptidase-IV; NEP, neutral endopeptidase 24.11; WEM, Williams E medium; BSA, bovine serum albumin; LC-MS/MS, liquid chromatography tandem mass spectrometry; UPLC, ultraperformance liquid chromatography; (M+H)$^+$, protonated molecular ion; CID, collision-induced dissociation; CL$_{int,app}$, apparent intrinsic clearance; $t_R$, retention time.
Abstract

Previous studies have revealed that the glucoincretin hormone glucagon-like peptide-1 (GLP-1)(7-36)amide is metabolized by dipeptidyl peptidase-IV (DPP-IV) and neutral endopeptidase (NEP) to yield GLP-1(9-36)amide and GLP-1(28-36)amide, respectively, as the principal metabolites. Contrary to the previous notion that GLP-1(7-36)amide metabolites are pharmacologically inactive, recent studies have demonstrated cardioprotective and insulinomimetic effects with both GLP-1(9-36)amide and GLP-1(28-36)amide in animals and human. In the present work, we have examined the metabolic stability of the two GLP-1(7-36)amide metabolites in cryopreserved hepatocytes, which have been used to demonstrate the in vitro insulin-like effects of GLP-1(9-36)amide and GLP-1(28-36)amide on gluconeogenesis. In order to examine the metabolic stability of the GLP-1(7-36)amide metabolites, a liquid chromatography tandem mass spectrometry assay was developed for the quantitation of the intact peptides in hepatocyte incubations. GLP-1(9-36)amide and GLP-1(28-36)amide were rapidly metabolized in hepatocytes from mouse (GLP-1(9-36)amide: $t_{1/2} = 52$ min; GLP-1(28-36)amide: $t_{1/2} = 13$ min) and human (GLP-1(28-36)amide: $t_{1/2} = 180$ min; GLP-1(28-36)amide: $t_{1/2} = 24$ min), yielding a variety of N-terminus cleavage products that were characterized using mass spectrometry. Metabolism at the C-terminus was not observed for both peptides. The DPP-IV and NEP inhibitors diprotin A and phosphoramidon, respectively, did not induce resistance in the two peptides towards proteolytic cleavage. Overall, our in vitro findings raise the intriguing possibility that the insulinomimetic effects of GLP-1(9-36)amide and GLP-1(28-36)amide on gluconeogenesis and oxidative stress might be due, at least in part, to the actions of additional downstream metabolites, which are obtained from the enzymatic cleavage of the peptide backbone in the parent compounds.
Introduction

The glucoincretin hormone glucagon-like peptide-1 (GLP-1) is derived from a proglucagon precursor and secreted by intestinal entero-endocrine L-cells in response to oral nutrient ingestion (Kieffer and Habener, 1999; Holst, 2007; Lovshin and Drucker, 2009; Mundil et al., 2012). The majority of circulating GLP-1 levels comprise the 30-amino acid peptide GLP-1(7-36)amide, which acts through a seven transmembrane-spanning, heterotrimeric class B G-protein coupled receptor on pancreatic β cells to exert glucoregulatory and insulinotropic actions (Thorens, 1992). However, after its secretion from the intestine, native GLP-1(7-36)amide is rapidly degraded (half-life ($t_{1/2}$) = 1-2 min) on its N- and C-terminus by the ubiquitously expressed enzymes dipeptidyl peptidase-IV (DPP-IV) and neutral endopeptidase 24.11 (NEP) (Hansen et al., 1999; Holst, 2007), respectively, to yield GLP-1(9-36)amide and nonapeptide GLP-1(28-36)amide as metabolites (Mentlein et al., 1999; Deacon et al., 1995a,b; Hupe-Sodman et al., 1995). In patients with type 2 diabetes mellitus, secretion of GLP-1 is diminished, and administration of either DPP-IV inhibitors (e.g., sitagliptin) or exogenous GLP-1 analogs (e.g., exenatide and liraglutide) represent potential therapeutic options in the treatment of type 2 diabetes mellitus (Moore and Saudek, 2008; Edwards, 2013).

Until recently, GLP-1(9-36)amide, the major circulating human metabolite of GLP-1(7-36)amide (Deacon et al., 1995a,b), was thought to be an inactive metabolite of GLP-1 due to its weak, if any, insulinotropic activity. However, growing evidence has suggested that GLP-1(9-36)amide possesses unique extrapancreatic insulin-like actions in the heart, vasculature, and liver, which appear to be mediated independently of the GLP-1 receptor (Abu-Hamdah et al., 2009; Tomas and Habener, 2010). For instance, in vivo administration of GLP-1(9-36)amide has demonstrated cardioprotective effects in dogs, rat, and mice, which arises from elevation in
myocardial glucose uptake, and from protection against ischemia-reperfusion injury (Nikolaidis et al., 2005; Sonne et al., 2008; Ban et al., 2008). Likewise, infusions of GLP-1(9-36)amide into obese, insulin-resistant human subjects significantly lowered hepatic glucose production in an insulin-independent fashion, suggesting that GLP-1(9-36)amide lowers plasma glucose in the insulin resistant subjects via direct inhibition of hepatic glucose production (Elahi et al., 2008). The NEP cleavage product GLP-1(28-36)amide also has been shown to inhibit weight gain, accumulation of liver triglycerides, and improve insulin sensitivity in diet-induced obese mice (Tomas et al., 2011a). Consistent with the in vivo observations, Tomas et al. (2010) recently demonstrated that GLP-1(9-36)amide suppressed glucose production in isolate mouse hepatocytes by 30% over a dose range of 0.1 to 100 μM independently of the GLP-1 receptor. Furthermore, in a follow-on study by the same authors (Tomas et al., 2011b), dose-dependent (0.01-10 μM) suppression of mitochondrial glucose production and oxidative stress by ~ 50% was also demonstrated in mouse hepatocytes with GLP-1(28-36)amide. In the case of GLP-1(28-36)amide, cytoprotective action was enhanced (0.1-100 nM) when a “solubilizing” formulation was used (Liu et al., 2012).

Towards this end, we became interested in examining the in vitro hepatocyte stability of GLP-1(9-36)amide and GLP-1(28-36)amide especially since hepatic endopeptidases including DPP-IV and/or NEP (Elovson, 1980; Roques et al., 1993; Yasojima et al., 2001; Itou et al., 2013), bear the potential to cleave the two GLP-1(7-36)amide metabolites into additional N- and C-truncated products with unique pharmacologic activity. In the present work, we have examined the metabolic stability of GLP-1(9-36)amide and GLP-1(28-36)amide in cryopreserved mouse as well as human hepatocytes using a novel liquid chromatography tandem mass spectrometry (LC-MS/MS) assay for the quantitation of intact GLP-1(9-36)amide and
GLP-1(28-36)amide, respectively, in the incubations. A facile decline of the GLP-1(7-36)amide metabolites in the hepatocyte incubations (e.g., $t_{1/2} < 1$ hour in mouse hepatocytes) led to a detailed characterization of their metabolic fate. Our in vitro findings raise the intriguing possibility that the inhibitory effects of GLP-1(9-36)amide and GLP-1(28-36)amide on gluconeogenesis and oxidative stress might be due, at least in part, to the actions of additional downstream metabolites, which are obtained from the enzymatic cleavage of the peptide backbone in the parent compounds.

Materials and Methods

Materials. GLP-1(9-36)amide (EGTFTSDVSSYLEGQAAKEFIAWLVKGRamide) and GLP-1(28-36)amide (FIAWLVKGRamide) were synthesized by solid phase synthesis and purified by sequential HPLC to >95% single component homogeneity. Description of the synthetic methodology is provided in the Supplemental Method section. Gibco William’s E Medium (WEM) supplemented with L-glutamine and without phenol red or sodium bicarbonate, pooled hepatocytes from human (pool of 10 livers from male/female), and pooled hepatocytes from male CD-1 mice were purchased from Celsis In Vitro Technologies (Baltimore, MD). Bovine serum albumin (BSA), sodium bicarbonate, diprotin A and HEPES were purchased from Sigma-Aldrich (St. Louis, MO). Phosphoramidon was purchased from R & D Systems (Minneapolis, MN). Solvents used for analysis were of analytical or HPLC grade (Fisher Scientific, Pittsburgh, PA).

Incubations in Hepatocytes. WEM was prepared by adding 26 mM sodium carbonate and 50 mM HEPES, followed by 0.2 µm filtration then 30 minutes of CO$_2$ bubbling at 37 °C. This media was used for thawing and suspension of hepatocytes. Stock solutions of GLP-1(9-36)amide and GLP-1(28-36)amide were prepared in water at 1 mM and diluted to 5 µM in
WEM. Incubations were conducted in 96-well flat-bottom polystyrene plate. Stability assessments were done in duplicate. Mouse and human hepatocytes were suspended at 0.5 million viable cells per ml WEM and prewarmed at 37 °C for 30 min. Incubations were initiated with the addition of peptide stocks (final concentration in incubation = 1 μM) and were conducted at 37 °C, 75% relative humidity, and 5% CO₂. The total incubation volume was 0.1 ml per well. To assess the role of NEP and DPP-IV in GLP-1(9-36) and GLP-1(28-36) cleavage, human hepatocyte stability of the two peptides was also examined in the presence of the NEP inhibitor phosphoramidon (1000 μM) and the DPP-IV inhibitor diprotin A (500 μM) (Gandhi et al., 1993; Roden et al., 1994; Ura et al., 1987; Turner et al., 2001; Malm-Erfjefält et al., 2010), respectively, in triplicate. Inhibitor concentrations were based on experiments described in aforementioned references, and were not optimized in the present work. Phosphoramidon was purchased as a solution in methanol, which was dried down then reconstituted in WEM prior to use. Aliquots (50 μl) of the reaction mixture at zero, 5, 10, 15, 30, 60, 90, and 120 min (time period associated with reaction linearity) were added to acetonitrile or ethanol (200 μl) containing terfenadine (MW = 472, 2.0 ng/ml) as an internal standard. The samples were centrifuged at 2000 x g for 10 min before LC-MS/MS analysis for the disappearance of the peptides. For the purposes of qualitative metabolite identification studies, the concentration of peptides in the hepatocyte incubations was raised to 20 μM. Reactions were carried out in 24-well polystyrene plates for approximately 2 half-lives. A non-enzymatic matrix control consisted of 10 mg/ml BSA in WEM. After quenching the incubation mixtures (1 ml) with acetonitrile or ethanol (3 ml), the solutions were centrifuged (2000 x g, 10 min), and the supernatants were dried under a steady nitrogen stream. The residue was reconstituted with the mobile phase and analyzed for metabolite formation by LC-MS/MS. For both stability and
metabolite identification studies, protein precipitation and LC-MS/MS sample wells that contained GLP-1(9-36)amide were pre-treated with an acetonitrile/BSA slurry to combat compound loss due to non-specific binding. Thus, 100 µl of a mixture containing 1 part 40 mg/ml BSA in water and 3 parts acetonitrile was added to wells of Eppendorf Protein LoBind deepwell 96 polypropylene plates. The plates were left uncapped overnight at room temperature to allow the mixture to evaporate. Similarly, GLP-1(9-36)amide hepatocyte incubation plates were soaked with an aqueous solution of BSA. A solution of 100 mg/ml BSA in water was added to 24-well (600 µl) and 96-well (100 µl) plates and allowed to sit overnight at room temperature. This solution was thoroughly aspirated from the wells and discarded prior to incubating. Low retention pipette tips (Thermo Fisher Scientific-Molecular BioProducts, Hopkinton, MA) were used throughout the operation. Acetonitrile was used for protein precipitation of GLP-1(28-36)amide and ethanol for GLP-1(9-36)amide.

**LC-MS/MS Methodology for Quantification of GLP-1(9-36)amide and GLP-1(28-36)amide.** Both GLP-1(9-36)amide and GLP-1(28-36)amide peptides were quantified on an ultra-performance liquid chromatography (UPLC)-MS system, consisting of a Waters Acquity UPLC (Milford, MA) interfaced with an AB Sciex QTrap 5500 Mass Spectrometer (AB Sciex, Framingham, MA) outfitted with a Turbo V ion source, operating in positive ionization mode. Briefly, samples were injected as is by partial loop injection and were separated from interferences on an Acquity BEH300 C18 column (50 x 2.1 mm, 1.7 µm) (Waters, Milford, MA) by gradient elution. The mobile phase consisted of 0.1% aqueous formic acid (solvent A) and 0.1% formic acid in acetonitrile (solvent B) flowing at 0.4 ml/min. The linear gradient program used was as follows: 10% B 0-0.5 min; 10-90% B 0.5-3.0 min, held at 90% B from 3.0-3.5 minutes, step back to initial conditions and hold for 1.0 minute. The most abundant precursor
ion for GLP-1(9-36)amide (protonated molecular ion \((\text{M+H})^+\) = 3088.5) under these experimental conditions was found to be the +4 charge state: \([\text{M+4H}]^{4+}\), \(m/z = 773.3\). This precursor was then fragmented by collision-induced dissociation (CID), where several selective product ions were observed. Those used for monitoring were 852.2 and 885.6. GLP-1(28-36)amide was monitored using its +2 charge state \([\text{M+2H}]^{2+}\), \(m/z = 545.1\) and product ions at 828.6 and 458.5, respectively. It should be noted that other similar instruments have demonstrated slight differences in the charge state of the most abundant precursor ions, so optimization on each platform is highly recommended for the purposes of quantitation.

Calibration standards were prepared separately for each matrix type using the same matrix pool as was used in the incubation samples to normalize for matrix effects. All standards were fit by least-squares regression of their areas to a weighted equation (linear for GLP-1(28-36)amide; quadratic for GLP-1(9-36)amide), from which the unknown concentrations were calculated. Dynamic range was 5.0-2000 nM for both analyses. Accuracy and precision were not qualified in these studies.

**LC-MS/MS Methodology for Metabolite Identification Studies.** Analysis of GLP-1(9-36)amide and its metabolites was performed using an Acella auto-sampler, degasser/pump assembly, photodiode array detector and an Orbitrap Elite mass spectrometer (Thermoscientific, West Palm Beach, FL). An Acquity UPLC BEH C18, 130Å, 1.7 µm, 2.1 X 150 mm column (Milford, MA) was used to achieve chromatographic separation. The mobile phase consisted of 0.1% aqueous formic acid (solvent A) and acetonitrile (solvent B) flowing at 0.3 ml/min. The linear gradient program used was as follows: 5% B 0-2 min; 50% B 25 min; 95% B 26.5-28.5 min; 5% B 29-34 min. The spray potential was 3.5 V and heated capillary was at 265 °C. Samples were analyzed in the positive ion mode by full scan mass measurements from 50-1000
amu at a resolution of 15,000, with one data-dependent acquisition scan of the most intense ion in scan event 1. Product-ion spectra were acquired at a normalized collision energy of 65eV with an isolation width of 2 amu.

Analysis of GLP-1(28-36)amide its metabolites was performed using a Surveyor auto-sampler, degasser/pump assembly, photodiode array detector, and an Orbitrap XL mass spectrometer (Thermoscientific, West Palm Beach, FL) operating in positive electrospray mode. A Phenomenex Hydro RP-C18, 3.5 μm, 150 x 4.6 mm column (Phenomenex, Torrance, CA) was used to achieve chromatographic separation. The mobile phase consisted of 0.1% aqueous formic acid (solvent A) and acetonitrile (solvent B) flowing at 1.0 ml/min. The linear gradient program used was as follows: 5% B 0-3 min; 10% B 3 min; 95% B 33-36 min; 5% B 38-45 min. The spray potential was 4 V and heated capillary was at 275 °C. Samples were analyzed by full scan mass measurements from 50-1000 amu at a resolution of 15,000, with two data-dependent acquisition scans of the most intense ion in scan event 1 and 2, respectively. Product-ion spectra were acquired at a normalized collision energy of 65eV with an isolation width of 2 amu.

The ProteinProspector tool v 5.10.11 (http://prospector.ucsf.edu/prospector/mshome.htm) (University of California, San Francisco, CA) was used for deconvolution of parent and metabolite full scan and daughter spectra. Standard methodology for elucidating fragment ions of peptides was applied. For example, fragments derived from the carboxy terminus were designated as “y” ions, whereas fragment ions derived from the amino terminal were designated as “b” ions (Wysocki et al., 2005). Likewise, “a” fragment ions corresponded to loss of CO from “b” fragment ions (Wysocki et al., 2005; Medzihradszky, 2005).
Data Analysis. Substrate disappearance $t_{1/2}$ and apparent intrinsic clearance ($CL_{int,app}$) were calculated using E-WorkBook 2011 (IDBS, Guildford, Surrey, UK). To estimate in vitro $CL_{int,app}$ of GLP-1(9-36)amide and GLP-1(28-36)amide in hepatocytes, the *in vitro* $t_{1/2}$ of GLP-1(9-36)amide or GLP-1(28-36)amide depletion was scaled using the following equation (Houston, 1994; Obach et al., 1997):

$$CL_{int,app} = \frac{0.693 \cdot ml \text{ incubation}}{t_{1/2} \cdot no. \text{ of cells in incubation}}$$

Incubation volume was 0.1 ml and cell density in the incubations was $0.5 \times 10^6$/ml.

Results

Hepatocyte Stability of GLP-1(9-36) and GLP-1(28-36)amides. To assess hepatocyte stability, GLP-1(9-36)amide and GLP-1(28-36)amide at a concentration of approximately 1 μM were incubated discretely in mouse and human hepatocytes at 37 °C for 2 hr. Periodically, aliquots of the incubation mixture were examined for depletion of the two peptides (Figure 1). Table 1 summarizes the $t_{1/2}$ and $CL_{int,app}$ for depletion of GLP-1(9-36)amide and GLP-1(28-36)amide in mouse and human hepatocytes. Co-treatment of human hepatocytes with the NEP inhibitor phosphoramidon (1000 μM) or the DPP-IV inhibitor diprotin A (500 μM) had virtually no effect on the stability of the GLP-1(9-36)amide and GLP-1(28-36)amide (data not shown).

Metabolic Profile of GLP-1(9-36)amide and GLP-1(28-36)amide in Mouse and Human Hepatocytes. Figure 2 depicts the extracted ion chromatograms of mouse (panel A) and human (panel B) hepatocyte incubations with GLP-1(9-36)amide (20 μM) conducted at 37 °C for 2 and 4 hours, respectively. A total of 13 and 10 metabolites were formed upon incubating GLP-1(9-36)amide in mouse and human hepatocytes, respectively. Table 2 indicates the retention time ($t_R$), molecular weight (monoisotopic protonated molecular ion (M+H)$^+$) and the observed charge
states of \((M+H)^+\) and peptide sequences for GLP-1(9-36)amide and its corresponding metabolites obtained in hepatocyte incubations. Native GLP-1(9-36)amide possesses a monoisotopic accurate mass of 3088.5738 \((M+H)^+\), which manifested as a +4 charge state \([M+4H]^4+\) of 773.8989 in the full scan MS spectrum. The CID spectrum of GLP-1(9-36)amide (Figure 3) generated several diagnostic C-terminus \(y\) fragment ions 934.8279, 885.8043, 852.1219, 751.7464, 722.3860 as well as the N-terminus \(b\) fragment ion 518.2261, respectively. Structural assignment of the various GLP-1(9-36)amide fragment ions is shown in Figure 3. It is noteworthy to point out that for GLP-1(9-36) and several of its larger peptide metabolites (e.g., metabolite M1), the theoretical mass values do not reflect the most prominent ion in the CID spectra. For example the theoretical value for the \(y23\) ion in GLP-1(9-36)amide is \([M+4H]^4+ = 851.7869\), reflecting the value of the \(^{12}\text{C}\) isotope, while the major peak in the CID spectrum of GLP-1(9-36)amide indicates a \([M+4H]^4+\) value of 852.1219 (Figure 3). This is because, for larger peptides, the \(^{12}\text{C}\) isotope does not have the highest isotopic distribution.

As seen in Table 2, all of the metabolites of GLP-1(9-36)amide were derived from cleavage across the peptide backbone. Metabolites M9 and M11-M13 were only observed in mouse hepatocyte incubations, whereas metabolites M1-M8 and M10 were observed in hepatocyte incubations from both species. The CID spectra of metabolites M1-M13 with structural assignments of observed fragment ions are depicted in Supplementary Figures 1-13 (see supplementary materials section).

Figure 4 depicts the extracted ion chromatograms of mouse (panel A) and human (panel B) hepatocyte incubations with GLP-1(28-36)amide (20 \(\mu\text{M}\)) conducted at 37 °C for 0.5 and 1.0 hour, respectively. A total of 5 (M14-M18) and 3 (M14, M17, M18) metabolites were formed upon incubating GLP-1(28-36)amide in human and mouse hepatocytes, respectively. Table 3
indicates the $t_R$, molecular weights [M+H]$^{+1}$ and/or [M+2H]$^{+2}$) and peptide sequences for GLP-1(28-36)amide and its corresponding metabolites obtained in hepatocyte incubations. GLP-1(28-36)amide ($t_R = 10.32$ min) possesses a [M+H]$^+$ of 1089.3804, which is observed in a [M+2H]$^{2+}$ charge state of 544.8400 in the full scan MS spectrum. The CID spectrum of GLP-1(28-36)amide (Figure 5) revealed diagnostic C terminus y ion fragments at 828.5206, 757.4833, 571.4039, 458.3196 and 414.7638. Corresponding N-terminus b (730.4291, 631.3606, 518.2762 and 261.1598) and a (233.1649) ion fragments were also noted. Structural assignment of the various GLP-1(28-36)amide fragment ions is shown in Figure 5 and Table 3. Metabolites M17 and M18 (observed in both mouse and human hepatocytes) were degradation products derived from cleavage of the peptide backbone in GLP-1(28-36)amide. Metabolite M17 ($t_R = 8.99$ min) possessed a [M+H]$^+$ at 941.6043, and its CID spectrum (Supplementary Figure 14) revealed diagnostic fragment ions (924.5776, 768.4764, 583.3598, 484.2914 and 371.2075), which was consistent with a peptide sequence IAWLVKGR (i.e., GLP-1(29-36)amide) derived from hydrolytic cleavage between the phenylalanine and isoleucine residues in GLP-1(28-36)amide. Metabolite M18 ($t_R = 7.25$ min) possessed a [M+H]$^+$ at 757.4832, and its CID spectrum (Supplementary Figure 15) revealed diagnostic fragment ions (740.4565, 584.3549, 527.3340, 441.2934, 399.2391, 342.2249 and 300.1708), which was consistent with a peptide sequence WLVKGR (i.e., GLP-1(31-36)amide) derived from hydrolytic cleavage between the alanine and tryptophan residues in GLP-1(28-36)amide. Finally, the molecular weights ([M+H]$^+$ and [M+2H]$^{2+}$) and CID spectra of metabolites M14 ($t_R = 13.20$ min), M15 ($t_R = 10.96$ min) and M16 ($t_R = 9.47$ min) (see Supplementary Figures 16, 17 and 18) indicated that they were glucose derivatives of GLP-1(28-36)amide and its downstream metabolites IAWLVKGR (M17) and WLVKGR (M18), respectively.
Discussion

Previous studies (Deacon et al., 1995a,b, 1996; Mentlein et al., 1993; Mentlein, 1999) have demonstrated that the DPP-IV-mediated proteolytic cleavage of native GLP-1(7-36)amide in human plasma involves the liberation of an N-terminus Xaa-Ala dipeptide and the concomitant formation of GLP-1(9-36)amide as the primary metabolite. The finding that GLP-1(9-36)amide circulates at appreciable levels in mammals is generally consistent with the role of DPP-IV in GLP-1(7-36)amide cleavage in vivo. Besides DPP-IV, the zinc metalloendopeptidase NEP also catalyzes the N- and C-terminus proteolytic cleavage of GLP-1(7-36)amide as evident from the formation of several metabolites (including GLP-1(28-36)amide) in incubations of GLP-1(7-36)amide with recombinant human NEP (Hupe-Sodmann et al., 1995). In mammals, both DPP-IV and NEP are present as soluble plasma enzymes and as membrane-bound proteins throughout the vasculature, and within various tissue compartments including hepatocytes (Elovson, 1980; Mentlein, 1999; Roques et al., 1993; Yasojima et al., 2001; Itou et al., 2013). It is therefore likely that hepatic proteases (including DPP-IV and NEP) can metabolize native GLP-1(7-36)amide and its downstream metabolites GLP-1(9-36)amide and GLP-1(28-36)amide generating structurally distinct N-terminal truncated peptides with potentially unique pharmacology. Against the backdrop of the recent data on the cytoprotective gluconeogenesis effects of GLP-1(9-36)amide and GLP-1(28-36)amide derivatives, respectively, in mouse hepatocytes (Tomas et al., 2010; Tomas et al., 2011b), we decided to examine their in vitro metabolic stability with an emphasis on characterizing novel downstream metabolites as such an endeavor had not been undertaken in the primary literature.

Our studies established that GLP-1(9-36)amide and GLP-1(28-36)amide derivatives were unstable in mouse and human hepatocytes yielding a variety of N-terminus cleavage products.
Metabolism at the C-terminus was not observed for both peptides. For GLP-1(9-36)amide, a total of 13 N-terminus cleavage products were observed in hepatocytes incubations. Some species differences were noted with respect to metabolites formed. For example, the formation of M9 (GLP-1(22-36)amide), M11 GLP-1(24-36)amide, M12 GLP-1(28-36)amide M13 (GLP-1(26-36)amide was observed in mouse but not human hepatocytes. In the case of GLP-1(28-36), two metabolites namely GLP-1(29-36)amide (M17) and GLP-1(31-36)amide (M18) were derived from peptide cleavage across Phe28-Ile29 and Ala30-Trp31 residues, respectively, and were detected in both mouse and human hepatocyte incubations. Metabolites M14, M15 and M16 were glucose derivatives of GLP-1(28-36)amide, GLP-1(29-36)amide (M17) and GLP-1(31-36)amide (M18), respectively, and were formed in human hepatocytes. In contrast, only the glucose derivative of GLP-1(28-36)amide was detected in mouse hepatocytes. While the identity of the enzyme(s) responsible for glucosidation remains unclear, it is possible that the sugar derivatives are formed via the action of uridine glucuronosyl transferases, which are known to catalyze N-glucosidation reactions on xenobiotics including drugs (Senafi et al., 1994; Toide et al., 2004; Obach et al., 2006). The precise regiochemistry of glucose adduction could not be deciphered based on the limited ion fragmentation for the three sugar metabolites. The N-terminus α-amino group on Phe28, the terminal ε-amino group in Lys34 amine and/or the guanidine group on Arg36 serve as plausible site(s) of glucosidation.

Because NEP demonstrates broad substrate specificity (Turner et al., 2001) and because it is expressed in the human liver (Yasojima et al., 2001), we decided to probe the role of this enzyme in GLP-1(9-36)amide and GLP-1(28-36)amide metabolism with the aid of the selective NEP inhibitor phosphoramidon (Turner et al., 2001). Inclusion of phosphoramidon in mouse and human hepatocyte incubations containing GLP-1(9-36)amide and GLP-1(28-36)amide did not
significantly impact the susceptibility of the two peptides towards proteolysis implying that hepatic NEP does not play a role in the metabolism of the two peptides. Overall, the finding (particularly in human hepatocytes) is consistent with the fact that no GLP-1(7-36)amide metabolites (including GLP-1(28-36)amide) formed by recombinant human NEP were detected in our human hepatocytes incubations with GLP-1(9-36)amide. Likewise, the DPP-IV inhibitor diprotin A failed to induce resistance towards proteolytic cleavage of GLP-1(9-36)amide and GLP-1(28-36)amide in mouse and human hepatocytes. This observation is consistent with our preliminary findings that demonstrate the rat, dog and human plasma stability of GLP-1(9-36)amide and GLP-1(28-36)amide ($t_{1/2} > 240$ min in all species). Under identical experimental conditions, the $t_{1/2}$ of GLP-1(7-36)amide in rat, dog and human was estimated to be 44, 150 and 100 minutes, respectively. Overall, these studies imply that plasma/hepatic DPP-IV activity does not appear to play a role in the metabolism of the two GLP-1(7-36)amide peptide metabolites. As such, additional mechanistic studies will be required to identify the endopeptidase(s) responsible for the metabolism of GLP-1(9-36)amide and GLP-1(28-36)amide in rodent and human hepatocytes.

The findings that GLP-1(9-36)amide and GLP-1(28-36)amide suppress excessive gluconeogenesis \textit{ex vivo} (and \textit{in vivo} in animals and human), suggests that GLP-1(9-36)amide- and GLP-1(28-36)amide-based peptides might represent a novel therapy for the treatment of excessive hepatic glucose production in individuals with type 2 diabetes as well as the excessive oxidative stress and insulin resistance of the metabolic syndrome. Clearly, the role of the downstream metabolites of GLP-1(9-36)amide and GLP-1(28-36)amide uncovered in our study will also need to be taken into consideration with regards to future pharmacology studies on these bioactive peptides.
Authorship Contributions

Participated in research design: Kalgutkar, Eng, Sharma, McDonald, Patel

Conducted in vitro experiments: Eng, Sharma, McDonald

Contributed new reagents or analytic tools: Eng, Sharma, Limberakis, Stevens, McDonald

Performed data analysis: Kalgutkar, Eng, Sharma, McDonald

Wrote or contributed to the writing of the manuscript: Kalgutkar, Eng, Sharma, McDonald

Figure Legends

FIG. 1. Depletion of GLP-1(9-36)amide (panel A) and GLP-1(28-36)amide (panel B) in mouse and human hepatocyte incubations.

FIG. 2. Extracted ion chromatogram of incubation mixtures of GLP-1(9-36)amide (20 μM) in mouse (panel A) and human (panel B) hepatocytes conducted at 37 °C for 2 and 4 h, respectively.

FIG. 3. CID spectrum of GLP-1(9-36)amide. Theoretical values of fragment ions (generated from the Prospector software) are depicted in the fragment ion assignment, which match the experimental values. In some instances, the $^{12}$C isotope does not have the highest isotopic distribution, which appears to cause a discrepancy in the observed versus calculated fragment ion values. For example, the y23 ion with the theoretical (M+4H)$^{+4}$ of 851.7869 ($^{12}$C isotope) is observed as a (M+4H)$^{+4}$ of 852.1219 ($^{13}$C) in the CID spectra.

FIG. 4. Extracted ion chromatogram of incubation mixtures of GLP-1(28-36)amide (20 μM) in mouse (panel A) and human (panel B) hepatocytes conducted at 37 °C for 0.5 and 1.0 h, respectively.
