Abstract

Organic Cation Transporter 1 (OCT1) plays a role in hepatic uptake of drugs, affecting in vivo exposure, distinguished primarily through pharmacogenetics of the *SLC22A1* gene. The role of OCT1 in vivo has not been confirmed, however, via drug-drug interactions that similarly affect exposure. In the current research we used Oct1/2 knockout mice to assess the role of Oct1 in hepatic clearance and liver partitioning of clinical substrates and assess the knockout model for predicting an effect of OCT1 function on pharmacokinetics in humans. Four OCT1 substrates (sumatriptan, fenoterol, ondansetron, and tropisetron) were administered to wildtype and knockout mice and plasma, tissue and urine collected. Tissue transporter expression was evaluated using LC-MS/MS. In vitro, uptake of all compounds in human and mouse hepatocytes and into human OCT1- and OCT2-expressing cells was evaluated. The largest effect of knockout was on hepatic clearance and liver partitioning of sumatriptan (2 to 5-fold change), followed by fenoterol, while minimal changes in the pharmacokinetics of ondansetron and tropisetron were observed. This aligned with uptake in mouse hepatocytes, in which inhibition of uptake of sumatriptan and fenoterol into mouse hepatocytes by an OCT1 inhibitor was much greater compared to ondansetron and tropisetron. Conversely, inhibition of all four substrates was evident in human hepatocytes, in line with reported clinical pharmacogenetic data. These data confirm the role of Oct1 in the hepatic uptake of the four OCT1 substrates and elucidate species differences in OCT1-mediated hepatocyte uptake that should be considered when utilizing the model to predict effects in humans.

Significance

Studies in carriers of *SLC22A1* null variants indicate a role of OCT1 in the hepatic uptake of therapeutic agents, although OCT1-mediated drug-drug interactions have not been reported. This work used Oct1/2 knockout mice to confirm the role of Oct1 in the hepatic clearance and liver partitioning in mice for OCT1 substrates with reported pharmacogenetic effects. Species differences observed in mouse and human hepatocyte uptake clarify limitations of the knockout model for predicting exposure changes in humans for some OCT1 substrates.

DMD# 88781

Introduction

Data implicating the role of Organic Cation Transporter 1 (OCT1) in the hepatic uptake of therapeutic agents have intermittently emerged in the past two decades. In vitro, it was recognized that variants in OCT1 had decreased uptake of substrates, including clinical compounds such as metformin, following which it was demonstrated in the clinic that OCT1 function was related to metformin's glucose-lowering effect (Shu et al., 2003, Shu et al., 2007). While larger studies report conflicting results on the role of OCT1 function in metformin efficacy (GoDarts et al., 2011, Dujic et al., 2017), positron emission tomography imaging of ¹¹C-metformin has confirmed a role of OCT1 in at least metformin hepatic disposition by direct measurement of metformin uptake into the liver in humans in vivo, demonstrating a difference in liver exposure in subjects with and without OCT1 variant alleles (Jensen et al., 2016). Given that the liver is not the major clearance organ for metformin, large changes in the plasma exposure with differences in OCT1 function would not be expected, and indeed only minor effects of OCT1 variants on the plasma pharmacokinetics of metformin are observed clinically (Shu et al., 2008, Jensen et al., 2016). However, other therapeutic agents have been identified as OCT1 substrates in vitro, including sumatriptan, fenoterol, morphine, and 5_{HT3}-receptor antagonists, which *are* cleared via the liver in humans. For each of these, single studies have indicated an effect of OCT1 genotype on the plasma clearance in the clinic, in turn leading to altered pharmacodynamic effects (Tzvetkov et al., 2012, Tzvetkov et al., 2013, Matthaei et al., 2015, Tzvetkov et al., 2018). These data are in agreement with in vitro activity for the OCT1 variants; while there appears a substrate-dependent effect on in vitro activity for some variants, for each of the studied OCT1 substrates there are OCT1 alleles which demonstrate no active uptake (Tzvetkov et al., 2012, Tzvetkov et al., 2013, Matthaei et al., 2015, Tzvetkov et al., 2018). Change in systemic exposure in the clinical studies is demonstrated in carriers of these variants with no in vitro activity for the substrate.

While the effect of variants of *SLCO1B1*, encoding the protein OATP1B1, has substantial evidence for affecting in vivo exposure of OATP substrates, the drug-drug interactions (DDIs) with

DMD# 88781

OATP inhibitors are generally even larger, likely because these variants have reduced, but not completely abolished transporter function, and because of overlapping substrate affinity between OATPs in the liver (Shitara et al., 2013). Conversely, although the pharmacogenetic effects of OCT1 are in agreement with *in vitro* studies and have been exemplified with multiple substrates, DDIs involving OCT1 have not yet been identified with these same clinical substrates. The only DDI reported to involve OCT1 indicated an effect of verapamil, an OCT1 inhibitor, on the pharmacodynamic effect of metformin. However again, as the plasma clearance of metformin is not through the liver, plasma pharmacokinetic changes due to OCT1 inhibition were not detected (Cho et al., 2014). As of yet, no DDIs that affect the plasma clearance of an OCT1 substrate have been reported, which would significantly aid in further understanding the role of this transporter *in vivo*. Additional evidence of the role of OCT1 in hepatic clearance *in vivo*, even in preclinical species would aid in validation, particularly with the ability to assess *in vitro*-to-*in vivo* correlation and substantiate the effect of transporter function on systemic exposure with that on liver partitioning. As such, mice void of organic cation transporters have previously been used to evaluate and confirm the role of Oct1 in the clearance and tissue partitioning of metformin. Data in both Oct1 and Oct1/2 knockout mice confirmed a decrease in liver:plasma partitioning in the absence of Oct1 (Wang et al., 2002, Shu et al., 2007, Higgins et al., 2012). Changes in metformin clearance, however, could only be observed in mice void of both Oct 1 and 2, as clearance is predominantly reliant on Oct2 in the kidney. As such, the effects and utility of Oct1/2 knockout mice to predict the effect of OCT1 on the plasma exposure in humans has not been evaluated using clinical substrates eliminated by the liver. In this research, we sought to evaluate the pharmacokinetics of four known OCT1 substrates in Oct1/2 knockout mice, compounds for which clinical pharmacogenetic effects of OCT1 have been demonstrated, to confirm the role of Oct1 in the hepatic clearance *in vivo* and to assess the Oct1/2 knockout model for predicting effects of OCT1 function in humans.

Materials and Methods

Materials

Sumatriptan succinate, fenoterol hydrobromide, ondansetron hydrochloride, and tropisetron hydrochloride were purchased from Thermofisher Scientific (Waltham, MA). Metformin hydrochloride was purchased from U.S. Pharmacopeia (Rockville, MD). ^3H -sumatriptan and ^{14}C -metformin were purchased from American Radiolabeled Chemicals (St. Louis, MO). InVitroGRO HT medium, KHB and male human cryopreserved hepatocytes (lot BRB) were purchased from Bioreclamation IVT (Westbury, NY). Rodent Hepatocyte Thawing medium and mouse hepatocytes (lot MBL192) were purchased from Lonza (Walkersville, MD). Buffers for cell culture and uptake (Dubecco's PBS, HEPES, MES, NH_4Cl , calcium and magnesium free DPBS) were purchased from Thermofisher Scientific (Waltham, MA). Formic, acetic and trifluoroacetic acids, ammonium bicarbonate, digitonin, dithiothreitol, imipramine hydrochloride, verapamil hydrochloride, TritonTM X-100, sodium deoxycholate, β -casein and iodoacetamide were from Sigma-Aldrich (St. Louis, MO). The Thermo ScientificTM PierceTM BCA Protein Assay Kit was obtained from VWR International LLC. (Radnor, PA). Acetonitrile (HPLC grade) was from Fisher Scientific (Pittsburg, PA). Mass spectrometry grade Trypsin Gold was purchased from Promega (Madison, WI) (product # V5280). A Picopure[®] 2 system (Hydro Service and Supplies, Inc. Durham, NC) was used to produce purified water. All of the stable isotope labeled (SIL) (^{13}C and ^{15}N) proteotypic tryptic, purified and calibrated, peptide standards (SpikeTidesTM_TQL) were purchased from JPT Peptide Technologies (Berlin, Germany). The standards are supplied with a tryptic linker, used for determining concentration at time of manufacture, at the C-terminus and thus are added to samples before digestion in order that the linker be released. Solid phase extraction (SPE) cartridges were StrataTM-X 33u Polymeric Reversed Phase (10 mg/mL, part no. 8B S100 AAK) obtained from Phenomenex (Torrance, CA).

DMD# 88781

In vivo studies

Breeding pairs of Oct1/2^{-/-} mice were purchased from Taconic Biosciences (Rensselaer, NY) and a colony maintained with Taconic, from which all knockout mice were obtained. Age-matched wildtype FVB mice were also obtained directly from Taconic. Studies were carried out at Covance (Greenfield, IN) and were approved by the Institutional Animal Care and Use Committee. Groups of male mice (25-30 g, age 8-14 weeks) were administered sumatriptan succinate, fenoterol hydrobromide, ondansetron hydrochloride, and tropisetron hydrochloride both intravenously (2 mg/kg) via the tail vein and orally (5 or 20 mg/kg, in the case of fenoterol) by gavage. Following compound administration, serial blood concentrations were collected as dried blood spots. For tropisetron, blood was collected on DMPK-A cards, to prevent cleavage by plasma esterases. At the end of blood pharmacokinetic studies, nine tissues (liver, spleen, kidney, duodenum, heart, lung, brain, muscle and testes) were collected for transporter quantitation via LC-MS/MS. Separate groups of mice were housed 8/cage and administered each compound intravenously (2 mg/kg), following which urine was collected over 24 hours in metabolism cages. Additional groups were administered each compound intravenously (2 mg/kg), then sacrificed at timepoints for tissue collection to determine tissue concentrations (n=7-16/time point); tissues were collected and snap-frozen in liquid nitrogen. Nine tissues (liver, spleen, kidney, duodenum, heart, lung, brain, muscle and testes), blood, and plasma were collected at 0.75, 1.5, 2 and 3 hours following sumatriptan administration and four tissues (liver, spleen, kidney, duodenum), blood, and plasma at 0.75 and 2 hours following administration of fenoterol, ondansetron, and tropisetron. For tropisetron, plasma was collected in tubes pretreated with PMSF and blood was again collected on DMPK-A cards. All samples were stored at -80°C prior to analysis of either drug concentrations or transporter quantitation. In pooled animal groups in which urine was collected, creatinine was measured in both plasma and urine using an enzymatic assay, to determine recovery of urine over the time frame.

LC-MS/MS quantitation of transporter expression in mouse tissues

DMD# 88781

The membrane fraction from tissue samples was prepared using an adapted differential surfactant extraction method, employing two surfactants (Ramsby and Makowski, 1999). Following gentle homogenization, the tissues were treated with digitonin. After light centrifugation the pellets were treated with Triton™ X-100. For each sample extract the total protein concentration was measured using the Thermo Scientific™ Pierce™ BCA Protein Assay Kit, enabling 20 µg aliquots to be measured for analyzing by the LC-MS/MS targeted quantitative proteomic method (Fallon et al., 2013, Fallon et al., 2016, Khatri et al., 2019). Membrane/microsomal protein (20 µg) was pipetted into PCR tubes and evaporated in a ThermoSavant SpeedVac. To the tubes were then added 100 µL of 50 mM ammonium bicarbonate, 10 µL of 40 mM dithiothreitol, 10 µL of β-casein (0.5 µg/10 µL) and 13.3 µL of 10 % sodium deoxycholate (to give a concentration of 1 %). Samples were heated at 60 °C, shaking at 500 rpm, for 40 min in an Isotemp Thermal Mixer (Fisher Scientific) in order to denature and reduce. After cooling to room temperature, 135 mM iodoacetamide (10 µL) was added and samples were then incubated in the dark for 30 min at room temperature. One pmol of each SIL peptide was then added from SIL peptide mixes used routinely and prepared in the lab. The concentration of each peptide in the mixes was 1 pmol per 10 µL). 10 µL of 0.1 µg/µL trypsin in 50 mM acetic acid was then added to each sample to give a trypsin:protein ratio of 1:20 (w/w). Samples were vortexed and digested for 20 h at 37 °C, shaking at 300 rpm, in the Isotemp Thermal Mixer. Following the digestion period, the reaction was stopped by the addition of 10 % trifluoroacetic acid, such that the volume added was 10 % of the total reaction volume. The samples were then vortex mixed and the precipitate was pelleted by centrifugation at 13.3K x g for 5 min. After transfer of the supernatant to fresh tubes the samples were evaporated in the ThermoSavant SpeedVac for 10 min to remove residual acetonitrile present from the SIL peptide mixes. SPE was then performed on the samples using polymeric reversed phase 10 mg/mL cartridges. Conditioning was with methanol and purified water. After adding sample, the solid phase was washed with water. Peptides were eluted with 60 % acetonitrile/40 % formic acid 0.1 % into 0.5 mL Eppendorf Protein LoBind tubes. Eluate was evaporated in the ThermoSavant SpeedVac and reconstitution was with 50 µL of modified mobile phase A (0.1 % formic acid/acetonitrile, 98/2, i.e. changed from 1 % acetonitrile). The sample was

DMD# 88781

centrifuged at 13.3K x g for 5 min and the supernatant was transferred to a deactivated vial insert for analysis by nanoLC-MS/MS. A laboratory human liver microsome (HLM) (pooled, N=50) quality control (QC) digest was also prepared in duplicate with the samples.

Analysis was performed on a nanoACQUITY (Waters, Milford, MA) coupled to a SCIEX QTRAP 5500 hybrid mass spectrometer (Framingham, MA) equipped with a NanoSpray III source. Control was by Analyst 1.5 software (SCIEX) and nanoACQUITY UPLC Console. Mobile phase A consisted of 1 % acetonitrile and 0.1 % formic acid. Mobile phase B was 100 % acetonitrile. Injection volume was 0.1 μ L (0.04 μ g or 0.2 % of the 20- μ g sample). The trap column was a Waters Symmetry® C18, 2G-VM, 180 μ m x 20 mm, 5 μ m particle size (catalog number 186006527). Sample was trapped at a flow of 15 μ L/min of mobile phase A for 1 min. After elution from the trap column peptides were separated on a Waters BEH130 C18 column, 150 μ m x 100 mm, 1.7 μ m particle size (catalog number 186003550). Flow rate was 1.3 μ L per min. The gradient was 100 % of A to start, decreasing to 58 % at 24 min, 5 % at 24.5 min for 3 min and returning to 100 % at 28 min for 7 min, the total run time being 35 min. The temperature of the analytical column was 35 °C. MRM analysis was in the positive mode with the ion spray voltage being 4000. The nanospray was produced using a 20 μ m inner diameter (10 μ m tip) PicoTip emitter by New Objective (Woburn, MA). Data for MRMs specific to mouse Octs 1, 2 and 3 peptides and other mouse and human (applicable to the HLM QC) specific peptides, including for two membrane markers, was acquired. The relevant peptides used for each, heavy labeled, are in Supplementary Table 1. Equality of response between the SIL and unlabeled peptides for each MRM was assumed.

Generation of virally-transfected OCT1-expressing cells and uptake in vitro

Full length cDNA of human SLC22A1 (NM_003057) was synthesized and cloned into the pLenti6.3 vector. pLenti6.3 empty vector and pLenti6.3- OCT1 were transfected into a lentiviral package cell line Lenti-X-293T to produce lentivirus supernatants. HEK293 cells were then transduced with these two lentivirus supernatants respectively and a single clone was selected by blasticidin (5 μ g/mL) to

DMD# 88781

generate stable cell lines. OCT1 expression in HEK293 was confirmed by flow cytometry using antibody staining (Novusbio Cat#NBP1-51684). HEK-293 stably-transfected cells with pLenti 6.3-empty vector, pLenti6.3 -OCT1 were grown in 5% CO₂ at 37°C in DMEM supplemented with 10% FBS, 50 µg/mL gentamicin, and 5 µg/mL blasticidin. Cell lines were maintained in T-75 flasks, reaching approximately 80% confluence before being passaged twice weekly at 1:10 ratio (volume: volume).

HEK293-VC (vector control), -OCT1, and -OCT2 cells were seeded onto 12-well poly-D lysine plates at concentrations ranging from 3.42×10^5 to 7.22×10^5 cells/mL. (OCT2-expressing cells were previously generated in-house by plasmid transfection.) Three days post-seeding, the cells were washed twice with prewarmed pH 7.4 HBSS buffer and preincubated with or without OCT inhibitor, MPP⁺ (1 mM), for 10 minutes at 37°C. Following the preincubation, cells were treated with the desired substrate with or without inhibitor for 1 minute at 37°C. After 1 minute at 37°C, the cells were washed three times with ice-cold HBSS and extracted with 80% MeOH containing an internal standard mix for sample analysis via LC-MS/MS. A separate set of cells were used to confirm proper cell function using positive control substrate, ¹⁴C metformin, and protein concentration was determined by bicinchoninic acid method. Uptake was assessed in duplicate or triplicate in two separate experiments. Using the same experimental method, a range of substrate concentrations was used to assess the kinetics of each substrate in OCT1- and OCT2- expressing cells, using a time point of 1 minute at each concentration. Again, using a similar experimental method, a range of MPP⁺ concentrations was also assessed to determine the IC₅₀ for OCT1 and OCT2, using sumatriptan as a substrate over 1 minute.

In vitro assessment of lysosomal trapping of OCT1 substrates

In uptake experiments, MPP⁺ was used as the OCT inhibitor, due to its reported lack of effect on lysosomal trapping (Kubo et al., 2016), an additional mechanism by which cations can be sequestered into cells, depending on their physicochemical properties. The role of lysosomal trapping on the cellular uptake of OCT1 substrates was assessed in vector control cells. For initial assessment, HEK293-VC cells were plated on poly-D-lysine coated 12-well plates. Confluent cells (day 4) were rinsed 2 x with either

DMD# 88781

Dulbecco's PBS (DPBS) + 10mM HEPES or DPBS 10 mM MES and 20mM NH₄Cl and pH'd to 7.4 or 5.0, respectively. Cells were conditioned at either pH for 30 minutes at 37°C and then exposed to 25 nM test compound for two minutes in the same buffer and pH (pH 7.4 or pH 5). Following a 2-minute uptake, the cells were rinsed 2 x in cold calcium and magnesium-free DBPS and the intracellular contents extracted with 80% MeOH containing an internal standard mix for LC-MS/MS analysis. Furthermore, the effect of other OCT inhibitors, imipramine and verapamil, on uptake of OCT1 substrates was assessed. Although imipramine and verapamil are reported to potently inhibit OCT1 and OCT2, they are also reported to affect lysosomal trapping (Kazmi et al., 2013, Kubo et al., 2016). To further assess the role of lysosomal trapping on the uptake on OCT1 substrates and to distinguish the effect of these inhibitors on OCT1 vs. lysosomal trapping, uptake experiments were carried out similar to that using MPP⁺ above, using 100 μM imipramine or verapamil, in VC and OCT-expressing cells.

In vitro hepatocyte uptake

Uptake of all compounds was evaluated in cryopreserved primary mouse and human hepatocytes in suspension using the oil-spin method (Morse et al., 2015). Hepatocytes were thawed at 37°C and then placed in InVitroGRO HT medium (human) or Rodent Hepatocyte Thawing medium (mouse). Cells were spun down and reconstituted in KHB (Krebs-Henseleit Buffer) and viability was determined to be >85% by Trypan blue staining. The cells were then diluted to a density of 1.5 to 2 × 10⁶ viable cells/ml in KHB with 4% Bovine Serum Albumin (BSA). Uptake was evaluated from 0.25 to 60 minutes at 1 μM at 37°C in the absence and presence of 1 mM MPP⁺. All time points were evaluated in triplicate in two experiments. ³H-sumatriptan was used as a positive control in all experiments. Cells were prewarmed for 5 minutes prior to the initiation of uptake. To initiate uptake, an equal volume of 4% BSA in KHB containing twice the concentration of test article was added. 100 μl aliquots were removed at specified time points and added to microcentrifuge tubes containing 100 μl of a 8:1 silicone (1.05 g/ml) to mineral oil (1.015 g/ml) mixture (final density = 1.027 g/ml) and 100 μl of 5 M ammonium acetate, then

DMD# 88781

spun down using table-top centrifuges at 12,500 rpm for 15 seconds. Tubes were immediately placed on dry ice and stored at -80°C .

Determination of concentrations samples using LC-MS

For HEK samples, cells were lysed in 80/20 methanol/water for 5 minutes. Samples were loaded into a PCR plate containing 80:20 methanol cell extract:water with stable-labeled internal standard. Positive control samples were analyzed via scintillation. Tubes containing in vitro hepatocyte uptake samples were cut at the oil layer into 96-well deep well plates and an 80:20 methanol:water mix containing internal standard was added. Samples were sonicated for four hours on ice until the cells had lysed thoroughly. Tubes containing positive control samples were cut in a similar fashion and analyzed via scintillation. Concentrations were normalized by viable incubation cell concentration. The LC-MS method details for cold sumatriptan, fenoterol, ondansetron, and fenoterol are given in Supplementary Materials.

Data and statistical analysis

In vivo blood parameters were determined by noncompartmental analysis using Watson 7.2. Renal clearance (CL_R) was determined as Ae/AUC , where Ae represents the amount recovered in urine and AUC represents the area under the blood concentration-time curve (the mean AUC of animals administered the same dose of compound IV). The renal clearance was then corrected for creatinine recovery; the calculated CL_R values were divided by [calculated creatinine renal clearance/reported creatinine clearance]. Creatinine renal clearance was calculated as above, and 14 mL/kg/min was used as mouse creatinine clearance. Serum creatinine and creatinine clearance were similar in wildtype and knockout mice (Supplemental Figure 1). Mean hepatic clearance was determined as total $\text{CL}-\text{CL}_R$ (determined as one value for

DMD# 88781

each compound, due to pooled nature of urine samples). Bioavailability (F) was calculated as AUC_{PO}/AUC_{IV} , after accounting for differences in dose. Fraction absorbed and fraction escaping metabolism in the gut (FaFg) were determined as $FaFgFh=F$, where $Fh=1$ -hepatic extraction ratio, using 125 mL/kg/min as hepatic blood flow in mouse. Student's t-tests were used to determine statistically significant differences in pharmacokinetic parameters and tissue partitioning, using GraphPad Prism 8.1.1.

Following transporter expression LC-MS/MS analysis, MRM data processing was with MultiQuant 2.0.2 (SCIEX). One peptide was used to report protein concentration, with a second peptide, if available, being used as confirmation. Individual peptide concentrations were calculated from peak area ratios, for two MRMs summed, of unlabeled to corresponding SIL responses. Criteria for selecting peptides to report protein concentration included digestion stability, limit of detection (LOD) and quality control reproducibility (Fallon et al., 2013).

To determine statistically significant differences in uptake experiments, student's t-tests were used to compare absolute uptake in OCT-transfected cells to VC cells, and to compare uptake in OCT-transfected cells with and without inhibitor. In VC cells with and without each inhibitor, one-way ANOVA was used to compare uptake in the presence of each inhibitor to control without inhibitor. To distinguish the effect of inhibitors on OCT-mediated transport, the effect of each inhibitor on VC cells was considered and the resulting ratios representing OCT-mediated uptake were calculated as the ratio of [mean uptake in OCT1 cells with/without inhibitor] over [mean uptake in VC cells with/without each inhibitor]. Inhibitor IC_{50} values for OCT1 and OCT2 were determined in GraphPad Prism 8.1.1 with the following equation:

DMD# 88781

$$\% \text{ uptake} = U_{\min} + (U_{\max} - U_{\min}) / (1 + \left(\frac{IC_{50}}{[I]} \right)^{\text{slope}})$$

Where U_{\min} and U_{\max} represent the minimum and maximum uptake, respectively, and $[I]$ represents the concentration of inhibitor.

K_m and V_{\max} values for OCT1 and OCT2 were determined using the equation below:

$$Uptake = \frac{V_{\max} \cdot [S]}{K_m + [S]} + P_d \cdot [S]$$

Where V_{\max} and K_m represent the maximal rate of uptake and the concentration and half maximal rate of uptake, P_d represents passive diffusion and $[S]$ represents substrate concentration.

DMD# 88781

Results

Blood concentration-time profiles of all four substrates in wildtype and knockout mice are shown in Figure 1, and pharmacokinetic parameters in Table 1. Following IV administration, blood concentrations of all four substrates were higher in knockout mice compared to wildtype, and IV clearance was significantly lower in knockout mice compared to wildtype for every substrate, as shown in Table 1; however, effects were larger for sumatriptan and fenoterol than ondansetron and tropisetron. Renal clearance was significant and involved active secretion for sumatriptan, fenoterol and tropisetron. Oct1/2 knockout did not appear to affect renal clearance of sumatriptan or tropisetron, while that of fenoterol was decreased. After accounting for renal clearance, decreases in calculated hepatic clearance were observed for every compound. Following oral administration, exposure (AUC) was increased dramatically following oral administration of fenoterol in knockout compared to wildtype mice, and significantly increased following oral administration of sumatriptan and tropisetron, while no significant effect of knockout on ondansetron AUC was detected following oral administration. For comparison to previous data, the effect of Oct1/2 knockout on metformin in this colony of animals is shown in Supplemental Figure 2. Similarly to that reported, metformin total clearance and liver partitioning were decreased in knockout mice, and bioavailability was similar between wildtype and knockout mice (Higgins et al., 2012).

Tissue partitioning of sumatriptan is shown in Figure 2, and that of fenoterol, ondansetron and tropisetron in Figure 3. Effect of Oct1/2 knockout on liver partitioning of sumatriptan and fenoterol was evident, while minimal or absent for ondansetron and tropisetron, consistent with the smaller changes in hepatic clearance observed with the latter. Oct1/2 knockout did not consistently affect partitioning of sumatriptan into any other tissues collected

DMD# 88781

over the time course, conversely to that observed in the liver over time. No decrease in kidney partitioning of sumatriptan or tropisetron was detected, consistent with a lack of change in renal clearance. Conversely, for fenoterol, a decrease in kidney partitioning was observed, consistent with a decrease in fenoterol renal clearance. Uptake into the intestine was significantly decreased at one of two time points for fenoterol and tropisetron, following intravenous administration, suggesting an effect on intestinal secretion, which has been observed previously for cations in both Oct1 and Oct2 knockout mice (Jonker et al., 2001, Jonker et al., 2003). This effect on partitioning into the intestine was not apparent for sumatriptan. Blood:plasma partitioning was unaffected by Oct1/2 knockout for any substrate.

Oct protein expression in mouse tissues is shown in Figure 4. Oct1 was found expressed in the liver and kidney, while Oct2 was found predominantly in mouse kidney, and present in the duodenum and testes. In all tissues expressing Oct1 or 2, knockout depleted expression. Interestingly, Oct3 expression was found in tissues in which Oct1 and 2 were not detected or below the limit of quantitation, including spleen, heart and lung. While knockout did not affect Oct3 expression in spleen or heart, Oct3 protein was detectable in the lung in wildtype mice but not in knockout mice. As the OCT1 substrates are also substrates of other transporters, e.g. ondansetron is also a substrate of P-gp, we included assessment of change in expression of other known transporters using LC-MS/MS. No differences in any other monitored transporters (detailed in Supplemental Table 1) were determined between wildtype and knockout mice (data not shown), indicating differences in substrate disposition between wildtype and knockout mice can be attributed to knockout of Oct1/2.

Uptake of the four compounds into OCT1 and OCT2-expressing HEK cells is shown in Figure 5. Increased uptake of sumatriptan and fenoterol was evident in both OCT1 and OCT2-

DMD# 88781

expressing cells, with ratios from 2.5-14 over vector control cells. Concentration-dependent uptake and V_{max} and K_m values for sumatriptan and fenoterol are shown in Supplemental Figure 3A; OCT1 K_m values are similar to those reported previously (Matthaei et al., 2015, Tzvetkov et al., 2018). We are not aware of any previously reported K_m values for OCT2. For ondansetron and tropisetron, uptake in OCT1-expressing cells was significantly greater than vector control, and was significantly decreased in the presence of MPP+, although ratios over vector control were less than for sumatriptan and fenoterol. Uptake of neither ondansetron nor tropisetron was significantly different in OCT2-expressing cells, compared to vector control. Overall, absolute uptake of ondansetron and tropisetron into cells was much higher than that of sumatriptan and fenoterol, which was hypothesized to involve lysosomal trapping of the former. Accordingly, lysosomal trapping experiment results using NH_4Cl , shown in Table 2, indicate no effect on the uptake of sumatriptan or fenoterol into vector control HEK cells, suggesting no lysosomal trapping of these compounds. However, uptake of ondansetron and tropisetron were decreased in the presence of NH_4Cl , as much as the positive control imipramine, suggesting a role of lysosomal trapping in the partitioning of these compounds into cells. Furthermore, as shown in Figure 6A, uptake of ondansetron and tropisetron into VC cells was significantly decreased by agents affecting lysosomal trapping, imipramine and verapamil, and much less so by MPP+, which does not affect lysosomal trapping. Neither imipramine nor verapamil affected uptake of sumatriptan into VC cells, consistent with lack of effect by NH_4Cl . Uptake of fenoterol into VC cells was affected by both MPP+ and verapamil, to unknown mechanism, but unaffected by imipramine. Concentration-dependent inhibition of OCTs by MPP+ is shown in Supplementary Figure 3B. The IC_{50} for OCT1 was 608 μM and for OCT2 was 0.14 μM . As reported previously (Kido et al., 2011, Zhu et al., 2018), potent OCT inhibition was observed by imipramine and

DMD# 88781

verapamil, IC₅₀ values for OCT1 were 0.67 μ M and 10.1 μ M respectively and were 0.14 μ M and 0.11 μ M for OCT2 (data not shown). After accounting for the effect of all three inhibitors in VC cells, the ratios of uptake in OCT1 cells with/without inhibitor over VC cells with/without inhibitor are consistent with each inhibitor, and represent the effect of each inhibitor specifically on OCT1-mediated uptake, shown in Figure 6B. Importantly, while the ratios for ondansetron and tropisetron are < 2 for OCT1, they are consistent with each inhibitor and are clearly higher than the ratios for OCT2, which was approximately 1 for every inhibitor.

Uptake of each OCT1 substrate into human and mouse hepatocytes, with and without MPP⁺, are shown in Figure 7. In human hepatocytes, inhibition of uptake by MPP⁺ was evident for all compounds. Conversely, in mouse hepatocytes, uptake of sumatriptan and fenoterol were decreased similarly as in human hepatocytes, however, minimal or no inhibition was observed for ondansetron or tropisetron. Consistent with the effect of lysosomal trapping and uptake observed in HEK cells, accumulation of both ondansetron and tropisetron was greater in both mouse and human hepatocytes, compared to sumatriptan and fenoterol.

DMD# 88781

Discussion

The use of Oatp knockout mice have been demonstrated valuable for reproducing effects of decreased OATP function observed in the clinic with OATP substrates. This model has been found to be quite robust, with differences in plasma exposure greater than 10-fold in wildtype and knockout mice for some substrates, likely related to the increased function and expression of Oatps in rodents relative to human (Higgins et al., 2014, Salphati et al., 2014). The OATP substrates highlighted the concept that uptake could be rate-limiting for hepatic clearance and recent data indicate OCT1 represents an uptake mechanism that may also be rate-limiting for plasma exposure in humans (Tzvetkov et al., 2012, Matthaehi et al., 2015, Tzvetkov et al., 2018). Subsequently, recent recommendations on assessing the role of OCT1 in the clinic have been produced (Zamek-Gliszczyński et al., 2018a, Zamek-Gliszczyński et al., 2018b). As the role of OCT1 variants on the plasma clearance of more substrates is revealed, confidence in tools for assessing the *in vivo* role of OCT1 becomes increasingly relevant.

Of the four compounds assessed currently, the role of OCT1 in the clearance of fenoterol in humans is most clear in participants with null OCT1 variants (Tzvetkov et al., 2018); as fenoterol is administered via intravenous infusion, it can be concluded that the systemic clearance of fenoterol is indeed altered with changes in OCT1 function. While renal clearance was not measured in the clinical study, there is no reported expression of OCT1 in the kidney in humans, hence it is assumed that only changes in hepatic clearance resulted in the altered plasma exposure. The current results in knockout mice are in alignment with a decrease in hepatic clearance and liver partitioning with decreased Oct function, with a similar magnitude change in total clearance as that reported in the clinic of ~2-fold. The effect of OCT1 on the pharmacokinetics of sumatriptan in human is also clear, with the plasma AUC over 8 hours

DMD# 88781

following oral administration increasing ~2-fold in humans with null OCT1 variants (Matthaei et al., 2015). While in the clinic a change in hepatic clearance could only be inferred from the results following oral administration, here in the mouse model, we confirmed the role of Oct1 in the hepatic clearance of sumatriptan, through both plasma clearance and liver partitioning. After accounting for renal clearance and hepatic extraction in mice, the current data indicate the absorption of sumatriptan to be incomplete or lost due to intestinal metabolism. However, these data suggest the change in oral AUC to be restricted to changes in hepatic first-pass and that absorption/intestinal first-pass (FaFg) did not change. Absorption in humans is also incomplete, based upon calculated Fh (Fowler et al., 1991); however currently it is not known if OCT1 variants affect sumatriptan absorption in humans, as effects in the intestine and liver cannot be elucidated from oral data in humans. From the current data, it is concluded that Oct1 in the liver decreases the hepatic clearance and partitioning of fenoterol and sumatriptan, and that these compounds represent the best clinical probes for evaluation of OCT1-mediated DDIs in the clinic.

Clinical data on ondansetron and tropisetron are not as robust; plasma concentrations at 3 and/or 6 hours following oral administration were reported higher in patients with two null OCT1 variants (Tzvetkov et al., 2012). While the pharmacokinetic data are sparse, they did align with an enhanced pharmacodynamic effect, with decreased episodes of vomiting in patients with null variants taking these antiemetics. The knockout mice indicate a small, albeit statistically significant, role of Oct1 in the liver for these compounds and the decrease in hepatic clearance was only 18-27%, compared to that of 4-fold for sumatriptan. As a change in overall AUC in humans has not yet been reported with OCT1 null variants for ondansetron or tropisetron, a direct comparison between the magnitude of change in the knockout and in humans cannot be

DMD# 88781

ascertained. It is of interest, however, that the *in vitro* data in mouse hepatocytes would have predicted this smaller change in mice with these two substrates, with minimal change in the presence of an OCT1 inhibitor. Furthermore, in human hepatocytes, there was clear inhibition in the presence of an OCT1 inhibitor, which is consistent with the reported clinical data. Therefore, it is concluded that the lack of effect in the knockout model does not likely indicate a minor role of OCT1 for these substrates in humans, but instead a species difference in the Oct1-mediated hepatic uptake of these compounds. Species differences as well as substrate-dependence in OCT interactions are well-documented in the literature (Dresser et al., 2000). Previous *in vitro* investigation reported it difficult to detect both tropisetron and ondansetron in OCT1-expressing *in vitro* systems, although pharmacogenetic results on pharmacokinetics and pharmacodynamics were positive (Tzvetkov et al., 2012). In agreement with our results in human hepatocytes, we did find uptake in OCT1-expressing cells to be significantly higher than VC cells, although the ratios were low, consistent with previous data. We proposed that the lysosomal trapping of these two compounds result in a high background even in control cells *in vitro*, causing low ratios to be ascertained with MPP+, an inhibitor of OCT1 which does not affect lysosomal trapping. The subsequent experiments assessing lysosomal trapping results using both NH₄Cl and chemical inhibitors confirm this, and are in line with physicochemical properties of these two compounds (Table 2). Furthermore, after discerning the role of OCT1/lysosomal agents imipramine and verapamil on both vector control and OCT-expressing cells, there does appear a consistent OCT1-mediated effect with inhibitors that both do and do not affect lysosomal trapping. However, even though current *in vitro* data are in line with effects of OCT1 null variants in the clinic, given the sparse clinical pharmacokinetic data currently available and limitations due to

DMD# 88781

lysosomal trapping in vitro, confirmation for the effect of OCT1 on these two compounds in the clinic would be valuable.

The current data point out an obvious limitation of the mouse model, in that species differences in OCT1-mediated hepatic uptake appear evident. Additionally, this double-knockout model warrants evaluation of renal clearance, as Oct2 is the predominant form in the mouse kidney; collection of urine in mice can be technically challenging and may confound the understanding of effects on hepatic clearance, although the ability to assess liver partitioning somewhat mitigates this limitation. Furthermore, although available LC-MS/MS transporter data in human liver and kidney are in general agreement with the current mouse data, with OCT1 expression in liver and OCT2 predominant in kidney (Prasad et al., 2016, Drozdik et al., 2019), previous data in mouse Oct knockout models indicate that Oct1 can play a role in the renal excretion of cations, as demonstrated for TEA (Jonker et al., 2003). Even though expression may be lower than Oct2, the role of Oct1 in mouse kidney may be another mechanism of species difference, along with differences in the fractional excretion of any drug between mouse and humans. Additionally, while current protein expression data by LC-MS/MS indicate expression of Oct3 in the liver to be undetectable, Oct3 mRNA has previously been detected in mouse liver (Chen et al., 2015) and OCT3 is detectable in human liver, from recent LC-MS/MS expression data (Khatri et al., 2019). However, the effect of Oct3 knockout on liver partitioning of metformin in previous studies is conflicting, and in most human subjects, OCT3 protein was found at much lower protein levels than that of OCT1 (Drozdik et al., 2019). Data regarding uptake of these four clinical substrates currently investigated by OCT3 are not available, however, it appears that OCT1 is the predominant form in both mouse and human liver, from current data, and likely does not imply a role of OCT3 in the species differences currently

DMD# 88781

observed. Our current data do indicate lack of compensatory upregulation of Oct3 protein with Oct1/2 knockout, in any tissues assessed.

In conclusion, the current data in knockout mice support a primary role of Oct1-mediated hepatic uptake in vivo for sumatriptan and fenoterol. A minor role for OCT1 substrates ondansetron and tropisetron coincides with the minor inhibition in mouse hepatocytes and do not reflect in vitro results in human hepatocytes. These species differences need to be considered when using this model to predict a role of OCT1 in the hepatic uptake of other compounds, as does a potentially limiting effect of lysosomal trapping on in vitro investigations for OCT substrates. Human hepatocyte in vitro uptake appears to be the most predictive for initiating investigation into OCT1 pharmacogenetics in the clinic. The mouse model could be used for confirmation or mechanistic insight, as done here, however negative results must also be interpreted in concordance with uptake into mouse and human hepatocytes.

WT=wildtype

KO=Oct1/2 knockout

Cl=clearance (following IV administration)

V_{dss}=steady-state volume of distribution (following IV administration)

DMD# 88781

$t_{1/2}$ =blood half-life (following IV administration)

$f_{u_{blood}} * GFR = f_{u_{plasma}} / B:P$ *glomerular filtration rate in mice ($f_{u_{plasma}}$ determined in-house)

AUC_{0-∞}=area under the blood concentration-time curve (following PO administration, calculated from 0 to infinity)

C_{max} =maximum plasma concentration (following PO administration)

F=bioavailability

F_h=fraction escaping hepatic extraction

F_aF_g=fraction absorbed times fraction escaping gut extraction

B:P=blood-to-plasma ratio

* $p < 0.05$ using student's t-test, compared to WT

** $p < 0.01$ using student's t-test, compared to WT

*** $p < 0.001$ using student's t-test, compared to WT

NC=not calculated (<10% dose)

DMD# 88781

Table 2. Physicochemical properties, permeability and lysosomal trapping of OCT1 substrates.

	<i>LogD 7.4</i>	<i>Basic pKa</i>	<i>MDCK permeability (cm/sec*10⁻⁶)</i>	<i>Ratio control:NH₄Cl</i>
<i>Sumatriptan</i>	-1.24	9.5	1.0	0.36
<i>Fenoterol</i>	0.33	9.6	1.9	1.4
<i>Ondansetron</i>	2.11	7.3	58	4.5
<i>Tropisetron</i>	0.70	9.3	34	2.5
<i>Imipramine</i>	2.48	9.2	36	2.5

Imipramine was used as a positive control for lysosomal trapping
